S01 - Adaptation to environmental changes in trees through the lens of common gardens and genomics

Divergent early life-history strategies and climate sensitivity in Fir (*Abies* spp.) and Beech (*Fagus* spp.) provenances across Europe

Zeitler L¹, Stefanini C¹, Pistone A¹, Csilléry K¹

¹Swiss Federal Institute For Forest, Snow And Landscape Research Wsl

POSTER SESSION 1, **P01.011**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Abrupt collapse of forest ecosystems in response to heat and drought have been observed worldwide. One possible driver of these collapses is the lack of regeneration and low survival of trees in early life stages. While most research focuses on adult trees and production traits, early life stages offer insight into traits under strong environmental and potentially genetic filters.

In this study, we investigated early life-history traits including germination dynamics and phenology in fir (*Abies* spp.) and beech (*Fagus* spp.), a drought resilient and a drought sensitive species. We focused on two climate change-related stressors: shorter, warmer winters that reduce seed chilling, and warmer, drier springs that increase evaporative stress during seedling development. Using climate chamber experiments, we tested the effects of provenance and its climate and soil, seed family, and stratification (long vs. short) and temperature treatments (cool vs. warm/dry) on 34,147 seeds from 32 wild-collected provenances, averaging 10 families per provenance. Seedlings were observed every ~2.5 days over three months, covering development equivalent to the first natural growing season.

Short stratification delayed germination in both species, while heat accelerated it. *Fagus* showed reduced germination rates (i.e., the proportion of seeds that emerged with a shoot) under warm winter conditions, *Abies* maintained high germination rates despite reduced chilling and dryer and warmer springs. However, delayed

consequences of reduced stratification emerged later in development: in both genera, seedlings from some provenances exhibited halted growth under warming, revealing gene-environment interactions in establishment rates. *Abies* development was more influenced by provenance, suggesting stronger adaptive divergence, while *Fagus* showed more consistent growth across provenances, indicative of a greater colonization potential.

Provenance elevation and longitude were strongly associated with developmental responses of both genera, and adaptive trait variation was linked to soil conditions in *Fagus* and to precipitation and temperature extremes in *Abies*. These patterns point to local adaptation and species-specific vulnerabilities in the face of climate change.

Our findings show that early seedling development is shaped by both genetic background and environmental conditions, including winter chilling, spring water and heat accumulation. Predictive provenancing could help maintaining fir populations that rely on natural regeneration even under shorter winters and warmer/drier springs and summers expected in the future. In contrast, natural regeneration in beech could be further reduced under future climate change scenarios; a finding that is largely confirmed by recent research on adult beech trees. Our findings suggest that the introduction of foreign provenances would not have a better regeneration capacity either.

Estimating the demographic history of fir species (*Abies* spp.) and predicting their spatial patterns of genetic diversity

POSTER SESSION 1, **P01.004**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Past climatic fluctuations triggered large-scale range shifts of forest tree populations and created selection pressures that favored certain traits, such as increased tolerance to heat or cold. Indeed, several common garden studies of forest trees reported that seedlings from southern and drier provenances have higher drought tolerance than northern populations. Understanding the impact of past climatic changes is essential to predict the future evolutionary response of forest trees to ongoing and predicted climate change. Fossil pollen and genomic data are our richest sources of information about past population movements of forest trees. However, inherent differences between these two data types have impeded joint analysis. Indeed, fossil records have long been considered sufficient for "storytelling" but not quantitative analysis. Here, we develop a workflow for the spatio-temporal interpolation of pollen records and propose the first joint analysis of fossil pollen records and genetic data to infer past population size fluctuations and range changes and to understand their role in determining the contemporary distribution of genetic diversity in fir species (*Abies* spp.) across Europe and Asia Minor. We developed a statistical workflow based on a unique combination of Indicator and Regression

Kriging to infer the past population size fluctuations of fir species across a grid with a 32x32km resolution and at 500-year time-steps based on fossil pollen records from 241 sites and paleo-climate data since the Last Glacial Maximum (LGM). We used Leave One Out, 5-fold and hindcast cross-validation to assess model performance. We used the resulting time series of maps of population sizes as input for a two-dimensional stepping-stone coalescent model (gridCoal). The mean coalescence time of each grid cell provides an estimate of the spatial distribution of the neutral genetic diversity today. We compared these patterns with real data, which consisted of estimates of genetic diversity. We used two data sets; one with 56 populations from the Western Alps consisting of 300 SNPs and another with 24 populations across Europe and Asia Minor from a 10k SPET genotyping panel. Our workflow allowed us to estimate the species' long-term effective population size and migration rate following the post-LGM colonization. Further, it opens the path to detecting loci under selection using a biologically meaningful null hypothesis that accounts for the demographic history of the whole species. Finally, our workflow can also help identify potential areas as seed sources for future reforestation.

Evolutionary genomics unravels the responses and adaptation to climate change in a key alpine forest tree species

POSTER SESSION 1 - **P01.002**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Global climate change is increasingly intensifying biodiversity loss. However, it remains unclear whether the pace of evolutionary adaptation can keep up with rapid climate change across various taxa. Specifically, the relative significance and impact of genetic adaptation versus plastic responses in either facilitating or hindering climate change responses are largely unexplored. Forest trees, as foundational components, and primary carbon sinks in terrestrial ecosystems, play a crucial role in combating and mitigating the effects of climate change. Yet, their long lifespans, large body sizes, and often lengthy generation times make them particularly vulnerable to maladaptation under changing climatic conditions. Some climate-related threats may even emerge within the lifespan of individual trees. Understanding the adaptive strategies of tree species is therefore essential to inform conservation efforts and guide effective management under a changing climate.

Materials and methods: In this study, we focus on *Populus lasiocarpa*, a key dioecious tree species whose range includes the Hengduan Mountains of China, a global biodiversity hotspot known for its complex and heterogeneous environments. We constructed a de-novo chromosome-level reference genome of *P. lasiocarpa* and subsequently acquired whole-genome re-sequencing data from 200 individuals representing 22 populations across its natural distribution range. Additionally, we obtained RNA-seq data for experimental seedlings from western and eastern populations, reflecting adaptation to distinct thermal and waterlogging environments under both control and stress conditions in leaf and root tissues. With this comprehensive genomic and transcriptomic dataset, we examine the roles of long-term

natural selection, local environmental adaptation, and immediate gene expression plasticity in driving evolutionary adaptation to climate change in this species. Additionally, we integrate space-for-time approaches with machine learning to calculate the genetic offset and assess genomic vulnerability across the species' natural range.

Results and conclusion: Over historical timescales, our findings demonstrate that demographic dynamics, divergent selection, and long-term balancing selection have shaped and maintained genetic variation within and between populations. In examining genomic signatures of contemporary climate adaptation, we found that haplotype blocks, characterized by inversion polymorphisms that suppress recombination, play a crucial role in clustering environmentally adaptive variations. We further assessed the relative contributions of environmentally induced plastic responses, constitutive expression divergence between genetic clusters, and their interactions in driving gene expression variation and divergence. Notably, we observed a strong correlation between sequence divergence and constitutive differential expression among genetic clusters. Finally, by incorporating local adaptation, migration, and genetic load into our predictions of population-level climate change risks, we identified western populations—primarily distributed in the Hengduan Mountains—as the most vulnerable to climate change. These populations should be prioritized for conservation and management. Overall, our study advances understanding of the relative roles of long-term natural selection, local environmental adaptation, and immediate plasticity responses in driving evolutionary adaptation to climate change in keystone species.

FruitRescue: Large-Scale Fitness Phenotyping of Fruit Trees for Climate Resilience across multiple environments in Europe.

POSTER SESSION 1 - P01.006, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: To provide a comprehensive assessment of the vulnerability of fruit trees and their wild relatives to climate change, a European consortium of researchers called FruitRescue was formed. Bringing together experts on several emblematic woody perennial species and their wild relatives (apple, apricot, peach, grapevine, and olive), the consortium seeks to create a system for predicting how well these species adapt to different local environments.

Material and methods

Genomic offset will be calculated using various tools to predict local adaptation. To confirm these predictions, a European network of common gardens has been established and is being monitored. Phenotypic and phenological data from this trial is shared among the partners, curated, and stored in a SQL database for real-time access.

An R Shiny portal facilitates data upload via formatted CSV files, visualization through standardized plots, and data retrieval in

compliance with the MIAPPE (Minimum Information About a Plant Phenotyping Experiment) standard.

Results: The FruitRescue database is introduced here, together with an overview of the project's scope and the network of common garden sites set up in diverse environments. Focusing on apple trees as a case study, we describe the experimental design and the phenological and phenotypic traits currently available in the database. We also share preliminary results that could highlight potential patterns of local adaptation within this framework.

Conclusion

This unprecedented database will serve as a valuable resource for the scientific community, enhancing our understanding of how fruit trees respond to climate change in both wild habitats and agricultural systems. It will also provide crucial guidance for breeders seeking to develop climate-resilient varieties and for conservation managers working to protect the wild relatives of fruit trees.

Genomic assessment of existing resources and climate maladaptation risk in Scots pine: implications for forest management

Wachowiak W^{1,2}, Lasek M¹, Łabiszak B²

¹Institute of Dendrology, Polish Academy of Sciences, ²Faculty of Biology, Adam Mickiewicz University

POSTER SESSION 1 - **P01.010**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Forest trees profoundly influence ecosystem functioning, biodiversity, and climate stability globally. Due to their longevity, broad distribution, and stationary nature, trees harbor extensive genetic variation shaped by historical climatic fluctuations and local adaptation processes. Among these, Scots pine (*Pinus sylvestris* L.) stands out as a widespread and ecologically significant conifer across Eurasia. It displays a complex genetic architecture shaped by past demographic processes and present-day climatic gradients. In the context of accelerating climate change, understanding the genomic basis of local adaptation is essential for predicting how tree populations will respond and for guiding proactive forest management strategies, such as assisted migration and targeted seed sourcing.

Methods: We investigated patterns of genomic diversity and local adaptation in 76 Scots pine populations (N = 1281 individuals) spanning a broad latitudinal range across Europe. Using high-density SNP arrays and mitochondrial DNA (mtDNA) markers, we examined population structure and historical divergence across the species' range. Subset of samples along steep latitudinal gradient was used for environmental association analyses, including redundancy analysis (RDA), to identify genomic loci associated with key climatic factors, especially mean annual temperature. To assess future risks of maladaptation, we performed genomic offset analyses using both RONA and RDA-based approaches, projecting adaptive mismatches under future climate scenarios.

Results: Our analyses revealed the existence of two major genetic lineages, which diverged during the mid-Pleistocene. Remarkably, these lineages have persisted despite ongoing gene

flow via effective pollen mediated gene flow. However, they did not reflect the strict division of the population into the analyzed seed zones of the species. We identified numerous SNPs strongly associated with temperature, indicating robust local adaptation across environmental gradients. Notably, populations in Central and Northern Europe exhibited heightened genomic differentiation at adaptive loci, pointing to region-specific selection pressures and increased vulnerability to future climatic shifts. Genomic offset modeling highlighted considerable risks of future maladaptation, particularly for populations located at ecological and geographical range margins. Our results indicate that adaptive genetic shifts required to cope with projected climate scenarios may require centuries through natural selection alone, emphasizing significant adaptive constraints.

Conclusions: Our study demonstrates the coexistence of deep historical genetic structure and clear signatures of contemporary adaptation within Scots pine. The identification of climate-associated genomic markers provides valuable tools for climate-resilient forest management. Specifically, these markers can inform assisted gene flow, provenance trials, and selection of planting material suited to future climates. Importantly, our findings advocate for the integration of genomic data into conservation policies, to safeguard the long-term adaptive potential and ecological resilience of forest ecosystems. As environmental change accelerates, such genomic-informed strategies will be indispensable in sustaining the biodiversity and functional integrity of temperate forests across Europe.

Genomic Signatures of Drought Adaptation in Eucalyptus: A Phylo-transcriptomic Approach Across 50 Million Years of Divergence

Yates L¹, Blackman C¹, Humphreys J¹, Haliwell B¹, Brodribb T¹, Holland B¹, Butler J¹, Charleston M¹, Macdonald A¹, Edwards C¹

¹University Of Tasmania

POSTER SESSION 1 - P01.008, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

As climate change intensifies drought conditions worldwide, understanding the genomic basis of drought tolerance becomes increasingly critical for forest conservation and management. Eucalyptus presents an exceptional system to study adaptation to aridity, with species distributed across Australia's diverse climate gradient, from mesic to arid environments. This distribution represents multiple independent evolutionary transitions into drought-prone habitats, providing a natural experiment in convergent evolution.

Our study employs a phylo-transcriptomic approach to investigate whether repeated adaptation to drought has utilized similar or different genetic pathways across phylogenetically distant species pairs. We selected eight taxonomic sections spanning three major Eucalyptus subgenera, with each section represented by closely related species pairs from contrasting environments. Using a robust common garden experimental design, we subjected seedlings to controlled drought-recovery cycles and measured transcriptional responses alongside physiological parameters.

Dimension reduction analyses reveal that gene expression patterns, rather than genomic content, primarily characterize species differences in drought response with gene usage clustering according to phylogeny and climate of origin. Using novel Bayesian phylogenetic comparative methods specifically developed for transcriptome data, we formally incorporate phylogenetic relationships into gene and gene-isoform expression analysis, allowing us to detect convergent and divergent transcriptomic signatures of drought adaptation. This unified statistical framework permits estimation of phylogenetic signal for each gene while coupling across the transcriptome using regularization methods.

This study examines the genomic basis of adaptive resilience to water stress and addresses fundamental questions about the predictability of evolution: Do species repeatedly rediscover the same molecular mechanisms when facing similar environmental challenges, or do they find unique solutions? These insights contribute both to evolutionary theory and practical applications in developing strategies to maintain forest resilience under climate change.

Genotype–environment interactions underlying resistance to *Hymenoscyphus fraxineus* in European ash

Meger J¹, Ulaszewski B¹, Burczyk J¹

¹Kazimierz Wielki University

POSTER SESSION 1 - **P01.009**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The invasive fungal pathogen *Hymenoscyphus fraxineus* (HF) continues to cause widespread declines in European ash (*Fraxinus excelsior* L.) populations across Europe. Understanding the genomic and environmental determinants of resistance is essential for developing adaptive management strategies, particularly as climate change may alter disease dynamics. In this study, we analyzed whole-genome sequencing data from 320 ash trees sampled across 109 populations in Poland, representing a broad range of ecological and climatic conditions. A genome-wide association study (GWAS) identified 114 SNPs significantly associated with resistance to HF, with over 40% located on chromosome 14, suggesting a potential genomic hotspot under selection. Genomic prediction models based on Random Forest and subsets of $\geq 2,500$ SNPs achieved over 80% accuracy in predicting

tree health status, with peak performance (~91%) observed for extreme phenotypic classes. Incorporating bioclimatic variables—particularly those related to temperature and precipitation seasonality—further improved prediction accuracy by up to 8%, especially when training and testing occurred within similar environments. In contrast, model performance declined when applied across divergent environmental contexts, highlighting the complexity of genotype-by-environment (G×E) interactions.

Our findings underscore the power of integrating genomic and environmental data to elucidate the adaptive architecture of disease resistance in *F. excelsior*. This integrative approach offers valuable applications for resistance-informed breeding, targeted conservation, and enhancing forest resilience to emerging biotic threats.

Islands as model systems for evolutionary divergence: a case study of *Hypericum lanceolatum* on Réunion Island

Callarec R¹, Garot E¹, Rivière E², Palama T³, Fock-Bastide I¹

¹University Of La Réunion, ²CIRAD, ³University Sorbonne Paris Nord

POSTER SESSION 1 - **P01.007**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Islands are increasingly recognized as model systems to study evolutionary processes. Their geographical isolation from continental coasts promotes genetic divergence and the development of distinct evolutionary lineages. Young volcanic islands, in particular, with their rugged topography and high relief, offer a multitude of ecological niches that lead to high diversification and speciation. As such, islands like Réunion and Hawaii are renowned for their remarkable radiation and extreme polymorphism across various taxa. Understanding the molecular underpinnings of divergence in insular species is therefore critical to ensure the long-term conservation of island biodiversity.

Here, we explore morphological and molecular divergence patterns in *Hypericum lanceolatum*, an indigenous shrub endemic to Réunion Island. Two botanical subspecies are currently described: *Hypericum lanceolatum* subsp. *lanceolatum* from 550 to 1700m and *Hypericum lanceolatum* subsp. *angustifolium* from 1800 to 2900m. The large variation exhibited in *H.*

lanceolatum morphology across the elevational gradient raises basic questions: What traits most distinctly differentiate these morphotypes? To what extent do genetic divergence and environment drive these differences?

To address these questions, we conducted extensive field sampling across the island to encompass the full morphological range of the species. Molecular divergences were assessed by genotyping-by-sequencing, and phenotypic plasticity was evaluated through a common garden experiment. Our results reveal a continuum of genetic differentiation along the elevational gradient, consistent with current taxonomy delimitation. However, morphological traits showed high plasticity under controlled conditions, suggesting a strong influence of environmental factors.

This work provides a valuable framework for studying evolutionary responses to environmental gradients and has implications for the conservation of island endemic species under changing climatic conditions

Landscape Genomic Tool built on genotype-environment associations of truly wild olive trees sampled along a 13-degree north-south in the Western Mediterranean to Assess the Adaptive Value of Cultivars

Rocchetti L¹, Zunino L¹, Sarah G², Lamoumni O³, El Bakkali A⁴, Capblancq T⁵, François O⁵, Rhone B¹, Cubri P⁶, **Khadari B**¹

¹Cirad, ²INRAE, ³Université Cadi Ayyad, ⁴INRA, ⁵University of Grenoble Alpes, ⁶IRD

POSTER SESSION 1 - P01.012, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Crop wild relatives and landraces represent locally adapted germplasm, enabling landscape genomic studies to identify genomic signatures of environmental adaptation. The derived information from such studies can be used to evaluate cultivar's adaptive value. This approach can represent an advantageous opportunity particularly for perennial crops where multi-location field trials to test specific cultivar or new breeding clone adaptations are costly and time-consuming.

We applied this approach to olive trees (*Olea europaea* subsp. *europaea* var. *sylvestris*), leveraging truly local wild germplasm from 27 populations sampled along a 13-degree north-south gradient, covering regions in Southern France, Corsica, Spain, and Morocco.

Using capture sequencing data targeting more than 50 000 predicted genes, we identified candidate polymorphisms linked to climate and soil variables through genotype-environment associations (GEAs), allowing us to map the adaptive genetic variation of olive trees across the estimated species range in the western Mediterranean basin. These findings can inform sampling recommendations aimed at capturing wild adaptive diversity.

Building on these GEAs, we applied the RDA framework to predict the spatial genomic

offset of new genotypes, which in this case were represented by widely used cultivars of the domesticated olive tree (*Olea europaea* subsp. *europaea* var. *europaea*). For a set of cultivars, the prediction allowed to identify regions where adaptation could enhance local performance and reduce reliance on agricultural inputs. The model confirms a latitude-based correspondence between specific cultivars' growing environments and adaptive regions in the western Mediterranean. Additionally, it highlights the broad adaptive-genetic variation present in western wild genotypes, which is currently underrepresented in cultivated germplasm, emphasizing the need for conservation strategies and breeding utilization.

Given the co-occurrence of wild and cultivated populations in the same area, and the effective one-way gene flow from vegetatively propagated cultivars to sexually reproducing wild populations, we could pinpoint areas where the cultivar offset is minimal. In these regions, the coexistence of wild and cultivated genotypes is less likely to disrupt the GEA pattern thereby preserving the integrity of wild adaptive diversity.

Collectively, these findings offer valuable insights for developing in-situ conservation strategies for wild relatives and informing breeding programs to enhance environmental adaptation.

Local adaptation and Genomic vulnerability to climate change in oak species

Wang B¹, Liang Y¹

¹South China Botanical Garden

POSTER SESSION 1 - **P01.005**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Understanding the genetic basis of local adaptation and its influence on species' responses to future climate change is crucial for forest conservation. We integrated pan-genomic and environmental association analyses to investigate adaptive evolution in two widespread East Asian oaks, *Quercus variabilis* and *Q. acutissima*. High-quality genome assemblies of 22 ecogeographically representative accessions revealed 543,372 structural variations (SVs), highlighting their critical roles in shaping genomic structure and influencing gene expression. Genotype-environment association analyses identified polygenic adaptation patterns, with climate-associated single nucleotide polymorphisms (SNPs) and SVs distributed across distinct functional gene categories. Notably, SV-based selection signals showed minimal overlap with SNP outliers, suggesting that conventional SNP-centric approaches may overlook key adaptive elements. A significant finding was a 250-kb adaptive introgression hotspot on chromosome 9 (Chr9-ERF), containing eight ethylene-responsive factor (ERF) genes and enriched candidate SNPs. Population genomic evidence confirmed westward introgression of advantageous haplotypes from *Q. acutissima* into *Q. variabilis*, providing mechanistic insights into how interspecific gene flow enhances local adaptation.

To quantify climate vulnerability, we applied a tripartite genetic offset framework to assess genomic-environmental decoupling under future climate scenarios. Key findings include: 1) Marginal populations exhibited elevated extinction risks due to limited habitat connectivity and dispersal constraints; 2) Northern China showed disproportionately high reverse genetic offsets, indicating insufficient adaptive potential of extant genetic variation; 3) Climate-driven range shifts may disrupt established genotype-environment correlations even in currently well-adapted populations.

This study advances three critical dimensions of evolutionary conservation biology: First, it establishes SVs as indispensable components in deciphering adaptive landscapes, complementing traditional SNP analyses. Second, it demonstrates that interspecific introgression serves as an evolutionary "accelerant" for climate adaptation in long-lived trees. Third, our multidimensional offset model provides actionable metrics for prioritizing conservation efforts. By revealing how historical selection, standing variation, and gene flow jointly shape climate resilience, this work offers a genomic roadmap for predicting and mitigating anthropogenic climate change impacts on keystone forest species.

Multi-Omics Insights into Seasonal Adaptation and Resilience in *Prosopis cineraria*

Dubay B¹, Hazzouri K¹, Amiri K

¹KCGEB, UAE University

POSTER SESSION 1 - **P01.001**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In the face of accelerating climate change and increasing aridity, desert ecosystems serve as vital models for biological resilience. *Prosopis cineraria* (Ghaf tree), a legume native to hyper-arid regions of the Arabian Peninsula and South Asia, exemplifies this resilience as a keystone species. However, the molecular basis of its adaptive resilience remains largely unexplored. This study presents the first integrative seasonal multi-omics characterization of *P. cineraria*, combining genomic, transcriptomic, epigenomic, and phenotypic analyses to dissect two principal adaptive traits: carbon assimilation and flowering regulation. Our results highlight a C₃-C₄ intermediate photosynthetic strategy that becomes especially relevant during the peak heat season. This intermediate pathway is supported by the upregulation of PEPC2 and GLK1, among other genes, whose expression colocalizes with seasonally dynamic topologically associating domains (TADs) in the chromatin architecture—suggesting a higher-order regulatory integration of photosynthetic and thermal adaptation. Moreover, we observe a novel co-regulatory interaction between reproductive phenology and carbon assimilation. Epigenomic profiling of

flowering regulation demonstrates that *P. cineraria* exhibits biannual flowering, occurring from March to May and from September to November, each governed by distinct molecular pathways. Spring flowering proceeds via a vernalization-responsive mechanism, wherein CpG methylation silences VRN1, thereby derepressing VRN2 and VRN3, repressing FLC, and ultimately activating FT–FD-driven floral initiation. In contrast, autumnal flowering is regulated through an autonomous pathway marked by the enrichment of H3K4me3 and H3K27ac histone modifications at the FCA locus, promoting FLC repression in the absence of cold cues. This dual flowering strategy, combined with the C₃-C₄ photosynthetic strategy, underscores a sophisticated degree of temporal plasticity, enabling reproductive success across seasonally variable climates. Our study elucidates the genetic and epigenetic architectures underlying survival in hyper-arid environments and provides foundational genomic resources with translational potential for resilience breeding in C₃ leguminous crops, which offers an essential framework for sustainable adaptation in the Anthropocene.

Towards an integrative understanding of taxonomic diversity, climate adaptation, and introgression in Southeastern European white oak species

Groot Crego C¹, Nicorescu A¹, Kovacs G¹, Curtu A², Zhelev P³, Rellstab C, Konrad H¹, Szukala A¹

¹Austrian Research Centre For Forests, ²Transilvania University of Brasov, ³University of Forestry,

⁴Swiss Federal Research Institute WSL

POSTER SESSION 1 - P01.003, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Oaks (genus *Quercus* L.) are considered potential winners under future drier and warmer climates. The white oak species complex includes some of the most widespread oak species in Europe – *Q. robur*, *Q. petraea*, and *Q. pubescens* – and is strikingly diverse in Southeastern Europe, where a number of subspecies have been reported. However, the evolutionary processes underlying this taxonomic richness remain unclear. We hypothesize that climate adaptation and adaptive introgression during the divergence of white oak lineages play a major role. Our project features whole-genome resequencing (WGR) and leaf morphological data from over 70 populations sampled along a transect spanning from southern Switzerland and Northern Italy, through Southeastern Europe and Turkey to the Caucasus, including several white oak diversity hotspots. Sampling design includes pure and mixed-species stands, allowing us to disentangle ancient from recent hybridization and define the genetic composition of each lineage. With this dataset, we aim at investigating the demographic history and the extent and direction of gene flow among white oak lineages. To investigate the role of gene flow in driving local adaptation, we will identify candidate loci for climate adaptation

through genotype-environment association studies using publicly available climatic data, and test whether they are involved in hybridization, pointing to adaptive introgression. We will also focus on populations at the ecological range margins to assess white oak adaptive potential under future climates. Ongoing WGR analyses show clear genetic differentiation between species, but not among subspecies. The extent of introgression among species appears to vary among chromosomes, indicating a non-random distribution of introgressed material that is maintained in the population. Leaf morphology differentiates putative hybrids and species but struggles with minor lineages due to large within-species variation. These results suggest different stages of differentiation among white oak lineages, allowing for investigation into local adaptation on multiple evolutionary scales. This large-scale study combining genomic, environmental and phenotypic data will significantly contribute towards a better understanding of taxonomic richness and adaptive potential in white oaks, and in hybridizing, sympatric species complexes in general.

A higher load of deleterious mutations has a detrimental effect on tree growth

Piñeiro Portela R¹, Cahn L², Budde K³, Hurel A⁴, Theraroz A², Vendramin G⁵, Pinosio S⁵, Lesur I², de Miguel M, Plomion C², Pardo-Otero E⁷, Heuertz M², González-Martínez S²

Bordeaux, Bordeaux Sciences Agro, INRAE, ⁷Evolutionary Biology Research Group (GIBE), Center of Information and Communication Technologies (CITIC), University of A Coruña

MEETING ROOM 122+123, August 18, 2025, 10:30 AM - 12:30 PM

A high proportion of deleterious mutations in the genome is predicted to cause a reduction in fitness known as genetic load. In plants, most studies focus on how detrimental mutations increase as a consequence of population bottlenecks, for instance in cultivated species as a negative outcome of domestication or at the margin of species ranges. However, the actual adverse effect of genetic load on individual phenotypes remains little characterised, especially in wild plant species with large populations and long lifespans.

We estimated genetic load based on genomic data in populations of the conifer maritime pine (*Pinus pinaster*, Ait.) on the island of Corsica (two different datasets including 133,656 SNPs in 393 individuals and 10,185 SNPs in 334 individuals) and examined its association with phenotypic traits related to growth, phenology, and

water-use efficiency measured under common garden conditions. Deleterious genetic variants were predicted from genomic sequencing data using classic (SIFT, PROVEAN, SNPEff) and Artificial Intelligence-based (ESM-1v) methods.

Our results revealed a negative correlation between genetic load and tree height on the Mediterranean island of Corsica, thus suggesting a negative cumulative effect of deleterious mutations on tree growth at the regional scale. This association was further confirmed by a wide-range analysis including 464 individuals from 34 populations across the entire range of maritime pine in the western Mediterranean, Atlantic Europe, and North Africa. Our study is one of the first to experimentally demonstrate adverse phenotypic effects (reduced tree growth) of genetic load in a long-lived plant.

Adaptation to ash dieback disease in natural populations of European ash

Galanti D^{1,2}, Connor Tyler C¹, Biro A¹, Wengler M³, Wood D¹, Buggs R^{1,2}, Nichols R², Kelly L^{1,2}

¹Royal Botanic Gardens Kew, ²School of Biological and Behavioural Sciences, Queen Mary University of London, ³The Sainsbury Laboratory

MEETING ROOM 122+123, August 18, 2025, 10:30 AM - 12:30 PM

Natural tree populations are exposed to increasing threats from biotic and abiotic stressors. One recent case with large predicted ecological and economic consequences is ash dieback (ADB), a fungal disease currently decimating ash (*Fraxinus excelsior*) populations in the UK and northern Europe.

Although there is some evidence that European ash populations are already adapting to the disease via selection on standing genetic variation, it is still unclear 1) if this process will be fast enough to conserve populations and 2) if increased mutation rates in response to stress could generate resistance alleles quickly enough for adaptation.

Additionally, while nearly all plant adaptation studies to date have focused on small genetic variants, recent advances in long read sequencing are allowing the investigation of large structural variants (SVs) with potentially larger phenotypic effects. Under stressful conditions, processes such as transposon reactivation or increased recombination may also quickly generate large amounts of this type of genetic variation.

To investigate these questions and predict the prospects for ash in northern Europe, we phenotyped and sequenced three UK

populations, generating Illumina short-reads for approximately 950 trees born either pre-epidemic (adults > 30 years) or during-epidemic (juveniles < 7 years). We then assigned parentage and generated PacBio HiFi reads for approximately 300 trees between known parents and their offspring.

By means of Genome Wide Association, we screened for small variants associated with ADB resistance/susceptibility, using visual phenotypic assessments of disease severity and also the quantification of fungal DNA load from the short reads. Despite the well-known strongly polygenic nature of ADB resistance we identified alleles associated with disease damage and are now testing for 1) allele frequency shifts and 2) differences in mutation rates, before and after the arrival of the epidemic. Using HiFi reads, we are calling SVs in a pangenome framework to identify additional genetic bases for resistance and novel SVs in parent-offspring pairs. To address the mechanisms that may be responsible for the generation of novel SVs, we have also produced a curated transposable element annotation, that will allow us to pinpoint which SVs are the result of transposition vs other processes. All together this will provide fresh insights into how natural populations adapt to novel selective pressures.

Genomic signatures of climate-driven (mal)adaptation in an iconic conifer, the English yew (*Taxus baccata* L.)

MEETING ROOM 122+123, August 18, 2025, 10:30 AM - 12:30 PM

The risk of climate maladaptation is increasing for numerous species, including forest trees. Developing robust methods to assess population maladaptation remains a critical challenge. Genomic offset approaches aim to predict climate maladaptation by characterising the genomic changes required for populations to maintain their fitness under a changing climate. In this study, we assessed the risk of climate maladaptation in European populations of English yew (*Taxus baccata*), a threatened, long-lived forest tree species widely distributed in small patchy populations across Europe, the Atlas Mountains and the Near East. First, we found evidence of local adaptation to climate across populations by analysing 8,616 SNPs genotyped in 475 trees from 29 populations across the European *T. baccata* distribution, with 18.1% of genetic variance explained by climate and the identification of 100 unlinked climate-associated loci using genotype-environmental association (GEA). Second,

we evaluated the deviation of populations from the overall gene-climate association to assess variability in local adaptation or different adaptation trajectories across populations. Third, we predicted genomic offsets and successfully validated these predictions using fitness proxies from a nearly independent dataset of 26 populations planted under common garden conditions. Finally, we integrated information from current local adaptation and the genomic offset, with historical genetic differentiation and effective migration rates to show that high-altitude *T. baccata* populations face higher future vulnerability to climate change than coastal or other low-altitude populations. Our study demonstrates the practical use of the genomic offset framework, provides insights to improve it and highlights the need for a population-centred approach that incorporates additional statistics and data sources to assess credible climate vulnerability in wild plant populations.

When South meets North: the shaping of a contact zone in three boreal tree species

Herrera Egoavil M¹, Leal L⁴, Zhou Q^{1,3}, Milesi P^{1,3}, Lascoux M¹, Yildirim B²

¹Department of Ecology and Genetics, Uppsala University, ²Department of Cell and Molecular Biology, Uppsala University, ³Scilife Lab, ⁴Department of Zoology, Stockholm University

MEETING ROOM 122+123, August 18, 2025, 10:30 AM - 12:30 PM

Climatic oscillations during the Quaternary, particularly the Last Glacial Maximum (LGM, ~18,000 years ago), induced repeated expansions and contractions of species ranges, thereby shaping the current distribution of European species. During the LGM, most of northern Europe was completely covered in ice, leading to the isolation of several species in refugia located south or east of the ice sheet. As global temperatures increased and the ice sheet receded, populations from various refugia recolonized northern Europe, thus establishing extensive contact zones where previously isolated lineages meet. These contact zones, along with the analyses of genome-wide markers, provide information on unique genetic admixture patterns and offer important insights into the divergence history of populations.

A recent contact zone in central Scandinavia has been identified for several organisms, and its study has recently been extended to forest tree species. In this project, we perform a comparative analysis of the three most common forest tree species in Scandinavia: *Picea abies*, *Betula pendula* and *Pinus sylvestris*. First, we identified similar demographic histories, but varying levels of gene flow across species, with *P. sylvestris* showing the highest levels and *P. abies* the lowest. Most notably, we demonstrate the presence of two main genetic clusters within each studied species, overlapping in a shared contact zone between 60° and 63°N. This contact zone

also corresponds to the climatic transition between the two major environmental zones in Sweden, suggesting a role for environmental factors in maintaining the two main genetic clusters of these species.

Furthermore, we detected genomic barriers to gene flow and identified signatures of selection likely driven by adaptation to contrasting environments. Finally, we show that differences in gene flow levels lead to species-specific patterns of adaptive genetic architecture, providing empirical support for theoretical expectations about adaptation under gene flow. Thus, we conclude that a contact zone in central Sweden is present in the three species and is maintained by natural selection, despite ongoing gene flow between the two main genetically divergent lineages of each species.

In general, contact zones have proven to be a major source of information on past demography and the selection pressures undergone by different populations or taxa. Together with genetic data, they provide insight into the evolutionary mechanisms that maintain barriers to gene flow and the origin of current genetic diversity. We also highlight that the study of contact zones in forest tree species is crucial for predicting how natural populations may respond to ongoing climate change, provides a comprehensive view of the genetic composition of species, and allows the refinement of sophisticated breeding strategies based on genomic predictions.

S02 - Addressing new and long-standing evolutionary questions with linkage disequilibrium based approaches

A Linkage-Based Method to Detect Introgression in Polyploid Genomes

Tusso S¹, Schneeberger K^{1,2,3}

¹Ludwig Maximilian University of Munich, ²Max Planck Institute for Plant Breeding Research, ³CEPLAS: Cluster of Excellence on Plant Sciences

POSTER SESSION 3 - P03.005, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The detection of introgression in polyploid genomes remains a major challenge for evolutionary and genomic research, especially when working with short-read data. Most existing methods are designed for diploid organisms or rely on assumptions and resources, such as accurate phasing, that remain difficult to achieve in polyploid systems. To address this, we developed a linkage-based method that uses correlations among variants within genomic windows to detect ancestry and identify introgressed regions in polyploid species.

We applied this method to *Solanum tuberosum*, the cultivated tetraploid potato, which has a complex and only partially resolved evolutionary history. Numerous wild *Solanum* species, spanning a wide geographic range from Mexico to Argentina, are potential contributors to its genome. Introgression is believed to have taken place during both the initial Andean domestication and subsequent breeding. However, the identity and genomic impact of specific donor species remain poorly understood.

Our dataset included 827 whole-genome resequenced samples, encompassing a global diversity of 166 cultivars and

representatives from 78 wild species. Ancestry blocks were identified by clustering variants in linkage disequilibrium, allowing us to trace their origins to specific wild donors along the genome. We found pervasive but heterogeneous introgression across both chromosomes and cultivars, with certain wild species making disproportionately large contributions. We found that introgression from wild species strongly predicts levels of genetic diversity in cultivated genomes, underscoring its central role in shaping the genomic landscape of potato.

Despite this extensive admixture, introgressed segments predominantly cluster into a limited number of haplotypes, indicating reduced haplotype diversity despite the presence of multiple potential donor species. This pattern points to one or a few recent introgression events for most wild species, as evidenced by the extended sizes and recurrence of shared haplotype blocks. Overall, this framework provides a practical and scalable solution for studying ancestry in polyploids and offers insights relevant to crop breeding and evolutionary genomics.

Asymmetric gene flow and phenotypic clines across a European butterfly hybrid zone

Cama B¹, Decroly T², Fisher A³, Vila R⁴, Baird S⁵, Lohse K²

¹Department of Integrative Biology, University of California Berkeley, Berkeley CA 94720, US , ²Institute of Ecology and Evolution, University of Edinburgh, Edinburgh, EH9 3FL, UK , ³University of Montpellier, Montpellier, France , ⁴Institut de Biologia Evolutiva (IBE), 08003 Barcelona, Spain , ⁵Institute of Vertebrate Biology (IVB), Czech Academy of Sciences, Prague, Czech Republic

POSTER SESSION 3 - P03.014, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Hybrid zones are an important tool in evolutionary biology. The genomes of naturally occurring hybrids can reveal the direction of gene flow and the presence/absence of genomic regions that remain divergent in the face of widespread hybridization, so-called islands of divergence. Two European butterfly sister species, *Melanargia lachesis* and *Melanargia galathea*, differ in distribution and in phenotype but overlap in range within a narrow hybrid zone in the Pyrenees, where hybridization is frequent. Using a pilot dataset of wild-caught hybrids from this region, we systematically quantify phenotypic differentiation and gene flow between species. We achieve this via a novel approach, by using the state-of-the-art diem software to attribute ancestries to each

variant in the hybrid zone *Melanargia* genomes and produce a SNP-level genomic admixture map across different individuals. We overlay this information with a landmark-based quantitative analysis of wing size and colour pattern, and find wing phenotype to be strongly correlated with chromosome-level hybridization indices, potentially showing a strongly multigenic architecture for the measured traits. Hybridization patterns show that the direction of gene flow in the hybrid zone is asymmetric, favouring introgression from *M. galathea* into *M. lachesis* more so than the opposite. This is the first investigation into this hybrid zone's population genetics and lays the methodological foundations for future research into this system as well as similar ones.

Demographic inference given rampant background selection under a high deleterious mutation rate

Marcelle M¹, Matheson J, Hernandez U, Masel J

¹Masel Lab - University Of Arizona

*POSTER SESSION 3 - **P03.010**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

Linked background selection (BGS) is well known to reduce genetic diversity in a population via selection against deleterious alleles at linked loci. Relative to this phenomenon, unlinked BGS is widely considered to be negligible. It is thus frequently omitted from population genetics simulations, especially considering that the inclusion of unlinked BGS means tracking the whole genome rather than more efficiently examining only a smaller genomic window. Recent research by Matheson and Masel (2024) has shown, however, that under a realistically high deleterious mutation rate, unlinked BGS is not only significant, but it has a greater impact on neutral diversity than linked BGS. Hence, failing to include unlinked BGS may limit the accuracy of such simulations. This is particularly true when it comes to inferring

the demographic history of a population in the wake of a brief genetic bottleneck using its site frequency spectrum (SFS), which is a graphical depiction of the distribution of allele frequencies across the genome. Bottlenecks tend to increase the prevalence of recessive deleterious homozygotes, causing prolonged, intensified BGS. As a result, the SFS may mimic that associated with an extended population size reduction, even in the case of rapid regrowth, thanks to an enrichment for common variants rather than rare ones. My research aims to utilize the Masel lab's whole-genome forwards time simulation to investigate the demographic inference of a brief bottleneck under a realistically high deleterious mutation rate, considering how the inclusion of unlinked BGS may impact the SFS.

Ecological speciation in North Atlantic Redfish (Sebastes): Insights from whole-genome data

Davenport D¹, Kess T, Breech T, Bradbury I

¹Fisheries And Oceans Canada

POSTER SESSION 3 - P03.007, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Redfish (*Sebastes* spp.) in the North Atlantic offer an opportunity to study ecological speciation in a marine environment. While their Pacific relatives have undergone a massive radiation, only four species — *S. fasciatus*, *S. mentella*, *S. norvegicus*, and *S. viviparus* — occur in the North Atlantic, often occurring in sympatry. The genus contains numerous species that are depth-segregated, and along with cryptic morphology and complex life histories, present both evolutionary questions and fisheries management challenges. Using whole-genome sequencing, we explored the evolutionary history of these species and

examined genetic diversity, population differentiation and linkage disequilibrium (LD) to understand the diversification of redfish in the North Atlantic. We characterise hierarchical and ecological genetic divergence in North Atlantic redfish and identify heterogeneous signals of post-glacial secondary contact between nuclear and mitochondrial genomic data. We connect the importance of identifying the genetic basis underlying divergence of redfish to both evolutionary biology and sustainable resource management as climate change continues to alter ocean conditions.

Estimating very recent population split times using decay of IBD (identity by descent) sharing

Wall J¹

¹Oregon Health And Science University

POSTER SESSION 3 - **P03.011**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Standard models for estimating divergence times between populations suffer from several modeling shortfalls, including an inability to distinguish between genetic drift caused by small population sizes or longer divergence times, and the reliance on an unrealistic assumption of random mating within a population. Here we present a new method for estimating recent divergence times that utilizes information in shared identity-by-descent (IBD) segments within and between populations, and which is insensitive to assumptions about random mating or population size. IBD sharing can be thought of as an extreme form of linkage

disequilibrium caused by the shared inheritance of an extended haplotype. We apply our approach to whole-genome sequence data from Indian caste groups sampled from the Birbhum district in West Bengal (as part of the GenomeAsia 100K project), and estimate average divergence times (i.e., onset of endogamy) of ~10-20 generations ago between different self-identified Hindu caste groups. This is much more recent than previous estimates, and highlights the complex structure of population assimilation/mixing that highlights most of our species' history.

Filtering linked selection to improve LD-based demographic inference in heavily exploited Baltic cod (*Gadus morhua*) populations

Meng L¹, Endo Kokubun E¹, Mittermayer-Schmittmann F^{1,2}, Han K¹, Reusch T¹

¹GEOMAR Helmholtz-Zentrum für Ozeanforschung Kiel, Marine Evolutionary Ecology, ²GEOMAR Helmholtz-Zentrum für Ozeanforschung Kiel, Ocean Research and Technology Center - Data Technologies

POSTER SESSION 3 - **P03.008**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

A central assumption in population genomics is that selection affects local genomic regions while demography leaves global signatures. However, widespread linked selection—through background selection and genetic hitchhiking—can affect linkage disequilibrium (LD) patterns across the genome, biasing demographic inference and challenging this assumption. This issue is especially pronounced in systems under long-term directional selection, such as fisheries-induced evolution (FIE) in Eastern and Western Baltic cod, where the length at which 50% of Eastern Baltic cod females reach maturity has declined by over 40% since the 1990s, from ~40 cm to ~23 cm. LD provides insight into recent changes in effective population size (N_e), as it decays over time with recombination and thus reflects recent coalescent history. However, demographic models assume that genome-wide LD is shaped by genetic drift rather than selection, which is violated by strong selection --such as FIE -- that maintains long haplotypes and inflates LD independently of drift, thereby biasing N_e estimates. To address this, we apply extended haplotype homozygosity (EHH) based scans, which detect recent positive selection by identifying unusually long homozygous haplotypes indicative of

reduced recombination around selected alleles. We enhance the resolution of these scans by using Oxford Nanopore Technologies (ONT) long-read sequencing to improve haplotype phasing, allowing precise detection of selected regions in heavily exploited cod populations. By filtering out regions under recent selection, we aim to reconstruct recent N_e trajectories shaped primarily by demographic processes, anticipating a signal of the population collapse in the 1990s and later on partial recovery. As an additional goal, we investigate the dynamics of gene deletion polymorphisms in an Eastern Baltic cod time-series genomic dataset spanning from 1996 to 2025, some of which show preliminary associations with traits like reduced body size and circadian regulation. Overall, this work provides evidence of genome-wide responses to large-scale exploitation, and will hopefully allow us for a more accurate reconstruction of demographic history aware of pervasive selection and structural variation. Our framework may be broadly applicable to other wild populations affected by strong directional selection, highlights the need to consider the influence of genome architecture to demographic frameworks.

Historical divergence and secondary contact shape the distribution of genetic variation in a key glacial refugium

Gentile G¹, Franchini P¹, Momigliano P¹, Chiocchio A¹, Canestrelli D¹

¹Tuscia University

POSTER SESSION 3 - P03.013, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The Italian Peninsula, a major glacial refugium characterized by hotspots of intraspecific genetic diversity, represents a region of critical importance for conserving the adaptive potential of wildlife populations. Its southernmost region, the Calabrian Peninsula, harbours the highest levels of genetic diversity for several taxa, including *Rana italica*, a species endemic to the Apennine mountain ranges. Preserving the evolutionary potential of such taxa requires a detailed understanding of spatial patterns of genetic variation, which often reflect complex demographic histories. For example, following historical isolation, secondary contact zones can present elevated genetic diversity, a result of introgression between divergent lineages. Using genome-wide data, we investigated the genetic structure and diversity of *Rana italica* populations within and around Aspromonte National Park, located at the

southern tip of the Calabrian Peninsula. Despite the limited geographic scale of sampling, population structure analyses revealed two distinct genetic clusters and one admixed group. The admixed group has the highest levels of heterozygosity, yet much stronger Linkage Disequilibrium (LD) than the other two less diverse populations, a pattern characteristics of secondary contact zones. Demographic reconstructions, including LD-based approaches, also support a scenario of recent secondary contact. Our findings underscore the value of integrating population genomic and demographic analyses to inform conservation strategies, particularly in regions with complex biogeographic histories and high endemism. Such approaches are essential for the effective management and preservation of evolutionary processes in fragmented habitats.

Identification of novel toxin resistance genes in *Drosophila* via Experimental Evolution, GWAS, and CRISPR screening

Marconcini M¹, Cruchet S¹, Viswanatha R², Goswami S², Mohr S², Benton R¹

¹University Of Lausanne, ²Harvard Medical School

POSTER SESSION 3 - P03.003, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Insecticide resistance is a widespread challenge for the management of vectors transmitting pathogens and agricultural pests, requiring a better understanding of the genetic mechanisms underlying evolution of resistance. *Drosophila sechellia* is a compelling model for such studies as it naturally evolved resistance to octanoic acid (OA), an abundant chemical of its noni fruit host that is toxic for other insects, including close relatives *D. simulans* and *D. melanogaster*. We have used a multi-pronged strategy to identify genes contributing to OA resistance. We began by experimentally-evolving *D. simulans* strains with higher tolerance to OA, and determined the resulting genetic architecture. To identify specific candidate genes, we integrated this analysis with a genome wide association study of OA resistance in *D. simulans* as well as a genome-wide CRISPR selection screen upon OA exposure in *D. melanogaster* S2R+ cultured cells. We identified four candidate genes with diverse predicted molecular and

expression properties and validated their relevance through RNAi-mediated knockdown and transgene-mediated overexpression in *D. melanogaster*. Three of these genes increased OA susceptibility when knocked down, while the fourth promoted *D. sechellia*-like levels of OA resistance. Notably, two genes showed elevated expression in experimentally evolved strains, mirroring their higher expression in *D. sechellia* compared to other drosophilids. Population genetics analyses further suggest signs of positive selection in at least one gene's coding region. Finally, we examined the effects of loss-of-function mutations in *D. sechellia*. Our results hint at an adaptive role of these genes in shaping OA resistance both under laboratory conditions and during *D. sechellia*'s evolutionary history. This study emphasizes the power of integration of multiple genetic approaches to identify genes and cellular mechanisms underlying toxin resistance in insects.

Inferring population size history from both modern and ancient genomes using approximate bayesian computation

Jacques P^{1,2}, Nikolic N^{1,2}, Boitard S³

¹Université de Toulouse, Toulouse INP, CNRS, IRD, CRBE, ²UPPA, INRAE, AQUA, ECOBIOP, ³CBGP, Université de Montpellier, CIRAD, INRAE, IRD, Institut Agro Montpellier

*POSTER SESSION 3 - **P03.009**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

One of population genetics oldest challenges is the inference of effective population size (N_e), a central parameter that impacts the genetic diversity and resilience of a population. Population and conservation genetics are keenly interested in its estimation. The constant improvement of sequencing methods and the quickly growing amount of available genetic data have motivated the development of methods capable of screening vast quantities of whole-genome data to estimate past N_e trajectories for thousands of generations. Such algorithms include Sequentially Markovian Coalescent (SMC) approaches such as the PSMC (Li & Durbin, 2011) and MSMC (Schiffels & Durbin, 2014), but also methods based on Approximate Bayesian Computation (ABC, Tavaré et al. 1997). ABC methods use summary statistics to infer N_e , which allow them to take into account whole-genome data such as Single Nucleotide Polymorphism (SNP). The SNPs' abundance (how often a SNP is present in a population), their allele frequency distribution and linkage disequilibrium (how

allele frequencies at two SNPs are correlated) are good indicators of past population size. However, all those methods use modern DNA samples for their calculations. Ancient DNA, or DNA extracted from archeological samples, is a potential way to improve past N_e estimates by giving us a glimpse in the population' past genetic diversity. To test this hypothesis, we updated PopSizeABC (Boitard et al. 2016), an ABC method using whole-genome SNP data to infer past N_e trajectories, so that it can take into consideration DNA data from several time points. Using simulated modern and ancient DNA under various population' histories, we show that the addition of new summary statistics accounting for allele frequency variations across generations reduces prediction error. In the future, we plan to apply PopSizeABC to empirical data, using the European Eel (*Anguilla anguilla*) as a test species. The European Eel, being a species supposed to be panmictic, is an especially interesting model as both ancient and modern samples can be assumed to come from the same population.

Investigating the role of meiotic recombination in social insects - Termites adding an important piece to the puzzle

Everitt T¹, Rönneburg T¹, Elsner D², Olsson A¹, Liu Y¹, Larva T¹, Korb J^{2,3}, Webster M¹

¹Uppsala University, ²University of Freiburg, ³Charles Darwin University

POSTER SESSION 3 - **P03.004**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Meiotic recombination is an essential process in all sexually reproducing organisms as it increases the efficiency of selection. There is however great variation in recombination rate across the tree of life, with eusocial insects from the order Hymenoptera in the topmost range. An example is the honeybee which has recombination rate estimates ranging between 19-37 cM/Mb. It has been hypothesized that eusociality leads to selection for high recombination rates as this would increase the genetic diversity in colonies and reduce kin conflict. The association between eusociality and high recombination rate has however not previously been studied outside of Hymenoptera.

Termites belong to the order Blattodea, which is separated from Hymenoptera by 380 million years. As termites are eusocial insects, they are expected to have high recombination rates according to the aforementioned hypothesis. In this study we have sequenced 20 samples from two termite species with different levels of social complexity and estimated their recombination rates based on population linkage disequilibrium using the software packages LDhat and LDhelmet. The estimated recombination rates do not deviate from typical rates of non-social insects and are clearly lower than rates found in eusocial Hymenoptera. This shows that sociality is not always associated with elevated recombination and that an alternative explanation for the elevated rates

in eusocial Hymenoptera might be necessary. We hypothesize that the high recombination rates in eusocial hymenopteran insects are instead related to their skewed sex ratios of reproductive individuals. In hymenopteran colonies, there is usually a high number of haploid males that compete for mating with a single female, whereas termites typically have an equal number of reproductive males and reproductive females. In hymenopteran colonies, the haploid males can be seen as an efficient system for testing different haplotypes, as both dominant and recessive variants are expressed and unsuccessful individuals are lost without any cost for the colonies.

In this study, we have also analysed the distribution of recombination events across the termite genome. Many vertebrate genomes have recombination hotspots, which are 1-2 kbp regions of strongly elevated recombination rate. Hotspots have also been found in a butterfly species but not in most other insects studied so far. We have found strong evidence of hotspots in the termite genome, with 50% of the recombination events localized to <0.5% of the genome for both of the studied species. Both species also have full-length copies of the gene for the zinc finger protein PRDM9, which controls hotspot locations in many vertebrates. It is still unclear whether PRDM9 is active and has the same function in termites, but if it does, this could indicate a more ancient role of this protein than previously known.

Linkage disequilibrium based inference method reveals stable recombination hotspots in the house sparrow

Raynaud M¹, Ravinet M², Jensen H³, Johnston S¹

¹Institute of Ecology and Evolution, School of Biological Sciences, University of Edinburgh, ²Centre for Ecological and Evolutionary Synthesis, Department of Biosciences, University of Oslo, ³Department of Biology and the Gjørevoll Centre, NTNU

POSTER SESSION 3 - P03.006, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Meiotic recombination is a fundamental mechanistic feature of sex and an important evolutionary force. Yet, recombination rates and landscapes vary from species to chromosome level. Understanding the causes and consequences of this variation remains a major challenge. The PRDM9 protein has been identified as a major recombination modifier in several vertebrates, particularly mammals. It leads to the rapid turnover of recombination hotspots between populations. This protein is absent in many taxa, including birds, where recombination landscapes are evolutionarily stable. Without the confounding effect of PRDM9-driven hotspot turnover, this makes the avian family a relevant taxonomic group to investigate another important level of recombination variation: differences between male and female recombination rates, known as heterochiasmy. Among birds, the house sparrow (*Passer domesticus*) is an emerging model system for studying the causes and

consequences of recombination. We used linkage disequilibrium from whole-genome polymorphism data to investigate the fine-scale population recombination landscape in three wild Eurasian house sparrow populations. The degree of LD between variants reflects the variation in recombination rates along the genome, a key step in uncovering the genetic and mechanistic drivers of recombination. Analysis of these LD-based maps confirms the presence of stable recombination hotspots between the three sparrow populations, mainly located near promoter regions and CpG islands. With the forthcoming integration of pedigree data and single cell sequencing, I aim to identify the functional genomic features associated with recombination events, to distinguish between male and female recombination hotspots and to present first insights into the genetic basis of sex differences in recombination rates and hotspot usage in the house sparrow.

Detecting genomic incompatibilities and barriers during divergence with gene flow in *Formica* ants

Heidbreder P^{1,2}, Poikela N¹, Nouhaud P⁵, Puukko T¹, Lohse K⁴, Kulmuni J^{1,2,3}

¹Organismal and Evolutionary Biology Research Programme, University of Helsinki, ²Tvärminne Zoological Station, University of Helsinki, ³Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, ⁴Institute of Evolutionary Biology, University of Edinburgh, ⁵CBGP, Univ Montpellier, CIRAD, INRAE, IRD, Institut Agro Montpellier

MEETING ROOM 129+130, August 20, 2025, 10:30 AM - 12:30 PM

Two current goals of speciation research are to understand whether genomic barriers to gene flow persist after contact between divergent lineages, and to identify the loci underlying such reproductive barriers. Locating barrier loci in empirical data is difficult due to the necessity of understanding the often complex demographic history of focal taxa and the heterogeneity in evolutionary forces across the genome. Furthermore, when identified, barrier loci are usually studied in isolation of one another, yet theoretical models predict an important role for coupling or epistasis in barrier persistence. In one classical model of epistasis, the Bateson-Dobzhansky-Muller (BDMI) model, incompatibilities are thought to be easily eroded by gene flow. However, this is rarely tested. Here we show empirically that BDMIs are persistent barriers when speciation happens with gene flow. We take advantage of the *Formica* hybrid wood ant system and recent methodological developments to (i) map barrier loci showing reduced migration during divergence between two species with the demographically explicit scan gIMble. This analysis used four whole-genome sequences from each parental species (*Formica aquilonia* and *F. polyctena*) and (ii) identify candidate BDMIs in naturally occurring hybrids through an imbalanced recombinant haplotype frequency analysis using the X(2) statistic. The X(2) method is related to linkage disequilibrium methods in that it looks for non-random associations between alleles, specifically missing haplotype combinations at loci of known ancestry. Here we used 386 whole-genome sequences from a single hybrid population in Finland. We find that a large

number of both barriers and BDMIs are scattered across the genome, rather than a small number of clusters. Furthermore, candidate BDMIs partly overlap with the long-term barrier regions identified by gIMble. Intriguingly, candidate BDMIs show interconnectivity, and the number of pairwise interactions a BDMI has impacts how effectively it reduces gene flow: BDMIs with many pairwise interactions to other BDMIs tend to reduce gene flow more effectively than those with fewer interactions. Finally in regards to function, long-term barriers identified by gIMble arise outside regions of both gene coding sequences (CDS) and transposable elements. In contrast, regions where long-term barriers and BDMIs co-locate are significantly associated with introns. Our results draw attention to an underappreciated aspect of incompatibilities: the structure of the network in which they interact, which has evolutionary consequences. Furthermore, it suggests persistent BDMI loci may have specific molecular characteristics, for example acting as hub genes in molecular pathways. The overlap between candidate BDMIs and regions of no gene flow between species indicates that incompatibilities have persisted despite divergence with gene flow between the wood ant species. Finding that long-term BDMIs are significantly associated with intronic regions implies a potential role of alternative splicing or gene regulation in incompatibilities, rather than CDS divergence. Overall, our results highlight the underappreciated impact of multilocus BDMIs and the need to consider network connectivity of BDMIs in future work.

Genomic incompatibilities and admixture between oviparous and viviparous lizards at a hybrid zone

Hunter D¹, Capstick M¹, Gaggiotti O², **Elmer K**¹

¹University Of Glasgow, ²University of St Andrews

MEETING ROOM 129+130, August 20, 2025, 10:30 AM - 12:30 PM

Live-bearing young (viviparity) or to egg-laying young (oviparity) is one of the most fundamental alternative life history traits found in animals. Viviparity has arisen from oviparity many times in squamates, yet instances where interbreeding is found between different parity modes are exceedingly rare. Hybridisation between individuals of different parity modes must have also occurred early in the origins of viviparity, thus, hybridization between lineages of alternative parity modes can provide unparalleled insight to the genetic mechanisms of this evolutionary innovation. We studied a unique hybrid zone between oviparous and viviparous Eurasian common lizards (*Zootoca vivipara*) to examine the extent to which genomic incompatibilities inhibit hybridisation, their arrangement and linkage across the genome, and the fine-scale spatial patterns of their transition between parity modes. To do so we deeply evaluated the genome-wide variation within and among individuals using whole genome resequencing of 266 lizards. We found very

high levels of admixture between oviparous and viviparous genomic backgrounds across the full continuum of possibilities, including a relatively large proportion of individuals with intermediate ancestry proportions. Gene flow is symmetrical into both parental lineages. We found a very narrow cline width of 3 km between the parity mode lineages. Steepness of the cline differed between chromosomes and genomic cline outliers were found on all autosomes. Leveraging a previously generated high resolution linkage map for this species, we plotted recombination rate across the genome and found genomic regions of excess ancestry (viviparous and oviparous combined) did not differ from background. Overall, our findings suggest that hybridisation between these parity mode lineages is long-standing and isolating mechanisms (or lack thereof) are such that genomic incompatibilities are rare. These findings suggest that the evolution of viviparity involves gradual and genome-wide divergence.

Inferring the evolutionary history of *Caenorhabditis elegans* while accounting for its self-fertilising reproductive mode

Wang C¹, Lohse K¹, Andersen E², Hartfield M¹

¹Institute of Ecology and Evolution, University of Edinburgh, ²Department of Biology, Johns Hopkins University

MEETING ROOM 129+130, August 20, 2025, 10:30 AM - 12:30 PM

Self-fertilisation extensively influences the evolutionary history of hermaphroditic species, by reducing effective population size and effective recombination rate, and increasing linkage disequilibrium (LD). These effects are usually ignored in population genetic inference methods, which overwhelmingly assume outcrossing. Here, we investigated how strengthened LD affects the population structure analyses and demographic inferences in *Caenorhabditis elegans*, a predominantly self-fertilising nematode. We applied a recently-published method for jointly inferring the demographic history and the self-fertilising rate of different *C. elegans* population. Population structure analysis suggests that strains from different Hawaiian islands are more genetically divergent than strains outside Hawaii, with strains from Kauai, the most ancient islands

of Hawaii, exhibiting the highest level of intrapopulation divergence. Pruning variants based on pairwise LD reduced the genetic divergence among Kauai strains but had little effect on the general pattern of population structure. For the Big Island population from Hawaii, the demographic inference with self-fertilisation considered estimated a selfing rate of 99% and a population decline followed by a massive increase. Further investigations comparing methods with or without self-fertilization taken into account and on how extensive linked selection may bias the demographic inference will provide important information on how to best infer the evolutionary history of populations with unusual reproductive mode and/or strong LD caused by uniparental reproduction.

Integrating LD- and Coalescent-Based Approaches Reveal Stability-Driven Genetic Diversity in the Adaptive Radiation of Lake Tanganyika Cichlids

Souza Costa D¹, Salzburger W¹, Barth J¹

¹University Of Basel

MEETING ROOM 129+130, August 20, 2025, 10:30 AM - 12:30 PM

Fluctuations in effective population size (N_e) leave detectable signatures in the genome, particularly in linkage disequilibrium (LD) patterns across loci, offering a powerful tool to reconstruct demographic history in natural populations. Neutral theory suggests that larger, stable populations maintain greater genetic diversity due to reduced genetic drift. However, the relationship between population size and genetic diversity remains debated, especially in natural populations with variable demographic histories and selective pressures. Here, we apply and compare both, LD-based two-locus and coalescence-based approaches to explore how historical population dynamics have shaped the present-day genomic diversity in the adaptive radiation of cichlid fishes in Lake Tanganyika, the ecologically, morphologically and behaviorally most diverse cichlid assemblage in Africa.

Using whole-genome data from 620 individuals across 40 species, we capture deep-time dynamics through historical mutation patterns, while LD-based inference enables fine-scale resolution of recent demographic changes by leveraging allele frequencies correlations. Our LD analyses revealed that current N_e is strongly associated with ecological traits —

specifically habitat depth and trophic level, possibly reflecting ongoing ecological processes. Cluster analyses revealed five demographic groups, all of which show a strong population decline during Lake Tanganyika's largest water level drop (500–600 m below present), likely fragmenting the lake and its inhabitants into sub-basins. A positive correlation between genetic diversity and coalescent-based N_e stability supports the 'stability hypothesis', suggesting that species less affected by N_e fluctuations, such as bottlenecks, maintain higher genetic diversity. In contrast, LD-based recent estimates showed no such pattern and were more closely associated with ecological traits. In this scenario, ecological habitat choice, crucial to current connectivity, also influenced historical demographic patterns and diversity, with deep-water species showing higher current genetic diversity and greater susceptibility to population fluctuations from past lake-level shifts.

Our research underscores the importance of integrating and discussing multiple methods for investigating demography and elucidates the intricate mechanisms driving cichlid population dynamics with a critical role of the ecological context in adaptive radiation.

Utilizing linkage disequilibrium (LD) to improve signal to noise ratios in outlier analyses

Kemppainen P¹, Guillaume F¹

¹Organismal and Evolutionary Biology Research Programme Eco-Evolutionary Dynamics group, University of Helsinki

MEETING ROOM 129+130, August 20, 2025, 10:30 AM - 12:30 PM

Identifying genomic regions associated with fitness in natural populations is central to understanding and predicting how organisms evolve in a changing environment. This can be achieved by identifying outlier loci in empirical distributions of population genetic statistics such as polymorphism and divergence, through associations between genotypes and environmental variables or through allelic frequency changes associated with survival in artificial selection experiments. However, when genetic structuring is high, based on statistical association alone it is impossible to distinguish a locus that has high allele frequency difference between environments/experimental treatments due to selection from a locus where this is due to random genetic drift. This results in either high false positive rates or low statistical power. A second major challenge comes from the failure to account for non-independence between loci making corrections for multiple testing in high density SNP data unnecessarily conservative. Linkage disequilibrium network analysis (LDna) uses pairwise estimates of LD to partition correlated sets of loci into LD-clusters representing distinct phylogenetic signals in the data. The LD-clusters can for instance be associated with population structuring, chromosomal rearrangements, sex-determination and not the least selection. Recent studies have demonstrated that LD-network-based complexity reduction in combination with association analyses may offer a solution to

both challenges in outlier analyses. This is because selection is known to leave strong LD-signature in population genomic data, such that LDna can both reduce the number tests (complexity reduction) while simultaneously focusing on loci from that are the most likely to be involved in selection. However, LDna is impractical for large data sets because it relies on pairwise LD estimates. Furthermore, the underlying premise that SNPs close to selected loci are overrepresented among LD-clusters have not been explicitly tested in simulations. However, from simulated data we discovered that directly factoring the LD-structure surrounding individual SNPs in the test statistics from association analyses could improve the ability to predict both the association with and the physical distance from selected loci, circumventing the need for network-analyses. This method i) reduced false positive rates in nearly all simulated data sets, ii) allowed for the detection of outlier loci that are physically closer to selected loci and iii) when applied to empirical data from the three-spined sticklebacks, identified multiple outlier regions not found in previous LDna based analyses using only a fraction of the computational time. However, we also demonstrate that LDna can still play a central role in partitioning the significant SNPs into outlier regions as well as in understanding the correlation structure among them for instance caused by genome wide epistatic interactions.

A comprehensive representation of selection at loci with multiple alleles that allows complex forms of genotypic fitness

Gossmann T¹, Vellnow N¹, Waxman D²

¹Tu Dortmund University, ²Fudan University

*POSTER SESSION 1 - **P01.023**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Genetic diversity is central to the process of evolution. Both natural selection and random genetic drift are influenced by the level of genetic diversity of a population; selection acts on diversity while drift samples from it. At a given locus in a diploid population, each individual carries only two alleles, but the population as a whole can possess a much larger number of alleles, with the upper limit constrained by twice the population size. This allows for many possible types of homozygotes and heterozygotes. Moreover, there are biologically important loci, for example those related to the MHC complex, the ABO blood types, and cystic fibrosis, that exhibit a large number of alleles. Despite this, much of population genetic theory, and data analysis, are limited to considering biallelic loci. However, to the present, what is lacking is a

flexible expression for the force of selection that allows an arbitrary number of alleles (and hence an arbitrary number of heterozygotes), along with a variety of forms of fitness. In this work, we remedy this absence by giving an analytical representation of the force of selection that emphasises the very different roles played by the diversity of the population, and the fitnesses of different genotypes. The result presented facilitates our understanding and applies in a variety of different situations involving multiple alleles. This includes situations where fitnesses are: additive, multiplicative, randomly fluctuating, frequency-dependent, and it allows fitnesses which involve explicit gene interactions, such as heterozygote advantage.

A Simulation Study Utilising REvoSim to Investigate the Impact of Predation on Species Diversity Across Environmental Heterogeneity

Peacock C¹

¹University Of Manchester

POSTER SESSION 1 - P01.032, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Predation plays a pivotal role in shaping biodiversity patterns, particularly across environmental heterogeneity gradients, such as the latitudinal biodiversity gradient. This research replicates and expands upon the findings of Freestone et al. (2011), which demonstrated the increased negative impact of predation on species richness in equatorial environments. Utilising the software REvoSim, a spatially explicit eco-evolutionary simulation platform, we conducted 1,100 runs across a range of environmental heterogeneities (S1-S10, and S15) under two predation conditions (absent and evolving predators). These simulations provided data on species richness, population dynamics, and community structure under the various environmental and predator conditions. Our findings support the conclusions made by Freestone et al., showing that predation has a more significant impact on species richness at intermediate to high heterogeneity levels. However, our results show that species

richness plateaued as heterogeneity increased, rather than scaling linearly. The presence of evolving predators led to a reduction in species count, reduced maximum species population sizes, and a lower number of total organisms within the system. Conversely, measures of species evenness were found to be higher with predators present, indicating that predation helps balance community structure by limiting species dominance. These findings suggest that the relationship between species richness and environmental heterogeneity is constrained by underlying factors such as resource availability and carrying capacity, which in turn limit the negative effect of predation at the higher environmental heterogeneities. This research has significant implications to the fields of evolutionary ecology and conservation for maintaining biodiversity in more diverse environments, particularly in equatorial ecosystems.

An interpretable machine learning-based alternative to genome-wide association studies (GWAS), and its application in a wild population

W. Gravdal G¹, Jensen H^{2,3}, Burnett H^{2,3}, Muff S^{1,3}

¹Department of Mathematical Sciences, NTNU, ²Department of Biology, NTNU, ³Gjørevoll centre, NTNU

POSTER SESSION 1 - P01.034, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The identification of genetic markers associated with phenotypic traits remains a key objective in evolutionary biology as well as in medical research and animal and plant breeding, but studies in wild populations are still relatively rare. Traditional genome-wide association studies (GWAS) have known limitations, particularly for the analysis of complex traits. In addition, an often under-evaluated downside of GWAS is that they are exclusively based on p-values, which combine effect size and uncertainty and are thus unreliable measures of variable importance.

Materials and Methods: Here, we investigated alternative measures of variable importance for identifying associations between Single Nucleotide Polymorphisms (SNPs) and phenotypic traits. In particular, we used so-called “Shapley values”, which originally were constructed for simple regression models to capture the contribution of each individual variable to the amount of variance explained by the total model. Since SNP data typically involve far more markers (p) than data points (N), standard regression models fail. We therefore employed machine learning models including boosted regression trees (XGBoost) and ridge regression, both of which enable estimation of variable importance using Shapley Additive Explanations, or SHAP values.

The approach was tested on genomic data comprising approximately 70,000 SNP markers and phenotypic measurements of 4000 wild house sparrows (*Passer domesticus*) from an insular metapopulation off the Helgeland coast in northern Norway. The analysis was performed for three traits: body mass, tarsus length and wing length. As a comparison, we performed a classical GWAS using linear mixed models. In both approaches we accounted for population

structure. To assess and compare the quality of SNP-trait associations identified by GWAS and SHAP, we also simulated phenotypes based on additive genetic models for a range of genetic architectures, and performed GWAS and SHAP analyses on the simulated traits.

Results: SHAP results give complementary information to GWAS, with the two methods showing little overlap in the SNPs identified as important. GWAS identified no SNPs surpassing the strict Bonferroni-corrected significance threshold for the three highly polygenic traits in the house sparrow system, illustrating its limited power under genetic architectures and sample sizes common for studies of wild populations. This result is consistent with the result from our simulation studies, where GWAS and SHAP were unable to identify associated regions for highly polygenic traits. On the other hand, both GWAS and SHAP effectively identified SNPs linked to traits simulated under more oligogenic architectures. In addition, our analyses illustrate that SHAP values contain information about the genetic architecture of traits in a way p-values are not designed for. In particular, SHAP values estimate the phenotypic variance explained per SNP, which enable inference about how many SNPs contribute to different levels of phenotypic variance.

Conclusions: Motivated by the intrinsic limitations of p-values, we have suggested alternatives to GWAS for mapping genes underlying variation in phenotypic traits. Our findings suggest that importance measures based on SHAP that we here tested for boosted regression trees, as well as a linear model based on shrinkage, may offer a promising alternative for genomic inference compared to GWAS.

Comparison of classical and AI-based computational tools for predicting deleterious mutations in plants

Pardo Otero E¹, Bolón Canedo V², Piñeiro R³

¹Evolutionary Biology Research Group (GIBE), Center of Information and Communication Technologies (CITIC), University of A Coruña, ²Laboratory for Research and Development in Artificial Intelligence (LIDIA), Center of Information and Communication Technologies (CITIC), University of A Coruña,

³Evolutionary Biology Research Group (GIBE), Interdisciplinary Centre of Chemistry and Biology (CICA), University of A Coruña

POSTER SESSION 1 - P01.046, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Understanding the role of negative selection and the impact of unfavourable mutations on adaptation has become increasingly relevant in Evolutionary Biology. Deleterious mutations can accumulate as genetic load, reducing fitness and threatening the viability of organisms. Current approaches use bioinformatic methods for predicting mutational deleteriousness in order to estimate genetic load from genomic data. Conventional approaches estimate the effect of mutations based either on the evolutionary conservation of the mutated site or on the predicted impact on protein structure and function. Recently, artificial intelligence (AI) techniques have emerged as powerful tools for predicting mutational effects, offering new opportunities to refine genetic load estimates. However, the performance of predicting tools remains poorly explored in plants, with empirical studies mostly limited to cultivated and model species. In addition, most AI-based deleteriousness prediction methods are focused on human variants.

To address this gap, we performed a comparative evaluation of seven methods for predicting deleterious genetic variants in plants. First, we assessed three classical tools: SIFT, PROVEAN and SNPEff. Second, we included a supervised, plant-specific machine learning model: PPVED. Third, we evaluated ESM-1v, an unsupervised deep learning protein language model (PLM) trained on 98 million protein sequences, which has recently emerged as one of the top-performing models for predicting mutational effects. PLMs stand out for their ability to learn complex contextual patterns, and evolutionary and functional constraints underpinning protein sequence data via unsupervised training. This

allows capturing residue dependencies, structural relationships, and biologically meaningful signals without relying on labelled examples. The final two approaches align with current state-of-the-art practices and involve leveraging the internal sequence representations (embeddings) extracted from PLMs through two distinct strategies: (1) by using these embeddings as input features to train supervised models specifically for predicting the mutational effects of plant variants; and (2) extending this approach by combining PLM-derived features with scores from classical conservation-based methods, such as SIFT.

This evaluation was conducted using a curated dataset of 12,865 SNPs, functionally annotated as neutral or deleterious, in 6,172 protein sequences from 433 plant species, retrieved from UniProt.

Preliminary results indicate that PLM-based approaches, particularly those using mean embeddings as input features, outperformed classical tools in predicting mutational effects on the curated plant dataset. Moreover, combining PLM-derived features with SIFT scores consistently improved predictive performance across all strategies.

As a follow-up of this study, we will apply these novel methods to tree population genomic datasets, aiming to estimate genetic load and investigate its impact on plant phenotypic traits, an area that remains largely unexplored. This work contributes to evaluating the potential of AI methods for deleteriousness prediction and introduces a new framework for estimating genetic load from genomic data.

Crossovers and Consequences: Genomic Prediction Reveals Selection on Recombination Rates in a Natural Population

Aase K^{1,2}, McAuley J³, Burnett H^{2,4}, Jensen H^{2,4}, Muff S^{1,2}, Johnston S³

¹Department of Mathematical Sciences, Norwegian University Of Science And Technology, ²The Gjørevoll Centre, Norwegian University Of Science And Technology, ³School of Biological Sciences, University of Edinburgh, ⁴Department of Biology, Norwegian University of Science and Technology

POSTER SESSION 1 - P01.027, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Meiotic recombination during gamete formation is a fundamental evolutionary process. It is required to ensure proper chromosome segregation and promotes genetic diversity by shuffling alleles into novel haplotypes. This can create beneficial allele combinations and break up linkage between beneficial and harmful alleles, thereby facilitating adaptive evolution. However, high recombination rates also carry risks, such as introducing mutations at crossover sites, and potentially disrupting favorable allele combinations. Thus, recombination rates could affect individual fitness in opposite directions, suggesting a complex relationship with individual fitness.

Investigating the impact of recombination rates on fitness is complicated by the fact that identifying crossover positions during meiosis - and thus finding the crossover count - is only possible for individuals with genotyped offspring. This introduces a sampling bias which prevents measuring the recombination rates of individuals that are reproductively unsuccessful, excluding them from potential fitness analyses. Failure to account for these unmeasured individuals could potentially bias analyses of the fitness effects of recombination rates.

Materials and methods: We used a long-term house sparrow study system from northern Norway with extensive pedigree, genotype, and fitness data to investigate the relationship between individual recombination rates and fitness components. The genomic and pedigree data were leveraged to measure autosomal crossover count (ACC) in adult house sparrows, resulting in one ACC measure per genotyped parent-offspring pair. We estimated sex-specific individual breeding values for ACC by using the phenotypic ACC measures for each parent as responses in a genomic prediction model. The genomic prediction, implemented as a Bayesian G-BLUP model, allowed us to estimate these

breeding values in more than 2,600 phenotyped individuals, as well as in more than 2,900 additional individuals with no recorded genotyped offspring, correcting the aforementioned sampling bias and increasing the sample size of the subsequent fitness analyses.

We then related the estimated breeding values to sex-specific fitness components, including annual reproductive success and annual survival. As the individuals without ACC measurements had higher uncertainty in their estimated breeding values, we used measurement error modelling to account for the heterogeneous breeding value uncertainties.

Results: We found that individual ACC was related to male and female annual survival, with predicted annual survival peaking at intermediate breeding values for individual ACC. We also found weak evidence that males with intermediate breeding values had higher annual recruit production, but no evidence of a relationship with reproductive success in females. Altogether these results suggest potential stabilizing selection against extreme values of ACC, especially in male house sparrows.

Conclusions: We demonstrate that individual variation in recombination rates influences fitness in a wild house sparrow population, with evidence of stabilizing selection on ACC particularly in male house sparrows. To interpret this association, we consider possible underlying biological mechanisms. On the methodological side, we present genomic prediction as a tool to address sampling biases. This novel approach allowed us to investigate the fitness consequences of a trait that can only be directly measured in reproductively successful individuals and allowed us to include several thousand individuals in the analysis that would otherwise have been excluded.

Detection of eco-evolutionary dynamics in communities using Joint Species Distribution Models

Hermann R¹, Pantel J²

¹University Of Konstanz, ²Université de Franche-Comté

POSTER SESSION 1 - **P01.014**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biodiversity at the metacommunity scale is typically influenced by a number of environmental, spatial, biotic, and stochastic factors. At the same time, these factors impact the evolution of individual species, as sites present different local selection pressures and connectivity can impact gene flow and genetic drift. Identifying the relative impacts of environmental, spatial, biotic, and other drivers on community composition across spatial and temporal scales has been greatly facilitated by joint species distribution models, but these models have yet to consider the impact of microevolution on community composition. We used Hierarchical Models of Species Communities (HMSC) to analyze simulated data of populations and communities, including in a large evolving metacommunity

model, to establish whether HMSC can sufficiently quantify the contribution of phenotypic evolution for metacommunity composition. The models successfully partitioned variance contributed by environmental, spatial, and evolving phenotypic drivers, and also estimated site- and time-specific covariance. We also applied the HMSC with trait evolution model to an existing dataset studying trait change and community dynamics in an experimental aquatic plant system. With this approach, we demonstrated that JSDM models such as HMSC can be used to estimate effect sizes of trait evolution for community composition, and thus can reflect the numerous complex, interacting processes of the eco-evolutionary dynamics that operate in many natural systems.

Division of Labour in the Evolution of Group Exclusion

Liang W¹

¹Department Of Zoology, University Of Cambridge

POSTER SESSION 1 - **P01.045**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: During Major Evolutionary Transitions, the evolutionary interests of smaller units become aligned. This often occurs through high relatedness. Highly related groups can be formed either via low dispersal or via group exclusion of unrelated immigrants, but the latter has received less theoretical attention. I thus explore whether division of labour can facilitate the evolution of group exclusion.

Materials and methods: I built an infinite island model with dominance hierarchy. The dominant individual in a group produces $c(1-x)$ offspring, and each subordinate $p(1-x)$ offspring, where p determines within-group skew, and x is the exclusion effort. Then the offspring disperse with probability d , with a fraction k of dispersers dying in transit. Surviving dispersers successfully gain entry to a random patch with probability determined by local adults' exclusion effort. Adults then die with probability $1-(1-g)(1-x)$, where g is the baseline mortality rate, and x the exclusion effort. If a dominant dies and some subordinates survive, then a random surviving subordinate is selected to become the new dominant. The vacancies left by dead adults are then filled up by offspring drawn at random from the local offspring pool (including both native born and immigrant young). Those offspring that fail to obtain a breeding spot then die. Using the

model described above, I built equations that capture the fitness of each individual given their own traits, local trait and population trait. I used the direct fitness approach (a.k.a. the neighbour-modulated fitness approach) to include the effect of kin selection. I used an adaptive dynamic approach to find the direction of selection which was then used to determine equilibria.

Results: Evolutionary stable states (ESS) are characterized as open or closed depending on whether exclusion evolves.

Allowing for Dominance Hierarchy (even without skew) increases the parameter range over which closed ESS occur. The greater stability of closed ESS is a result of division of labour – in the parameter space where models without dominance hierarchy cannot form stable closed ESS, the model with dominance hierarchy yields outcomes in which some individuals breed while others work to exclude newcomers, analogous to the soma / germ divide.

Conclusions: Group exclusion is a common, spiteful action observed in nature, yet its theoretical implication is rather understudied. The results show that from simple assumptions, it is possible to generate patterns observed in nature. This suggests further studies into the consequence of group exclusion may be fruitful.

Estimating bacterial mutation rates with simulation-based methods (ABC)

Tauzin A¹, Frenoy A¹

¹Université Grenoble Alpes

POSTER SESSION 1 - **P01.021**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The mutation rate is a key parameter of evolution as it defines the speed at which genetic diversity is generated de novo. It is defined as the number of mutation occurring per base pair per cell division (equal to generation for asexual organisms). A traditional approach to estimate mutation rate for bacteria is the fluctuation test, which consists in growing bacteria in a non-selective medium for then plating them in a selective environment in order to reveal the number of mutants (survivors) carrying a resistance to that stress. A mathematical model is then fitted on these experimental data to infer mutation rate. However, model makes restrictive assumptions regarding the effect of the mutations on the fitness (no effect) and the growth conditions (no death in the culture) which probably do not represent reality.

The objective of our work is to develop a new simulation-based computational method for the inference of mutation rate from experimental data (fluctuation tests), taking into account non-standard demographics (death) and fitness effect of the mutation.

Our approach relies on Approximate Bayesian Computations: it consists in using a simulator combined with MCMC algorithms (Metropolis-Hastings) to find the parameters which best explain the experimental data.

We tested it on two types of tasks:

- estimation of 1 parameter : mutation rate, when other parameters (death rate and fitness effect) are known
- simultaneous estimation of 2 parameters : mutation rate and fitness effect or mutation rate and death rate.

As today, this method already provides encouraging results. It competes well with the reference tools (rSalvador, which uses the Ma-Sandri-Sarkar maximum likelihood estimator, and Flan's probability generating function) in simple scenarios where these tools work.

Due to its simulation-based nature, it can also generalize to more complex scenarios where these reference methods do not work.

EvAM-Tools: a tool for Evolutionary Accumulation Models

Díaz-Uriarte R^{1,2}, Herrera-Nieto P³, Pérez de Lema Díez J⁴

¹Universidad Autónoma de Madrid, ²Instituto de Investigaciones Biomédicas Sols-Morreale (IIBM), CSIC-UAM, ³Department of Macromolecular Structures, Centro Nacional de Biotecnología (CNB-CSIC),

⁴Escuela Politécnica Superior, Universidad Autónoma de Madrid

POSTER SESSION 1 - P01.022, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Cancer progression models (CPMs) and evolutionary accumulation models (EvAMs) were developed to discover dependencies in the irreversible acquisition of binary traits from cross-sectional data. They have been used in computational oncology and virology but also in widely different problems such as malaria progression and antimicrobial resistance. These methods have been applied to predict future states of the system, identify evolutionary routes of feature acquisition, and improve patient stratification, and new methods continue to be developed. Despite their existing applications and their promise for evolutionary-based treatments and therapeutic target choice, these methods are not widely used. A possible reason is the difficulty, for end users, to have easy access to experiment with the different methods to understand their assumptions and implications, as well as the lack of access to the existing state-of-the-art implementations. For developers, the difficulty of comparing and benchmarking existing and new approaches is also a likely hindrance.

Results: EvAM-Tools is an R package and Shiny (<https://shiny.rstudio.com/>) web app, also available as Docker images, that provides a unified interface to state-of-the-art EvAMs. It allows users to:

- Run state-of-the-art EvAMs, including Conjunctive Bayesian Networks (CBN ---and their MC-CBN version---), Oncogenetic trees (OT), Mutual Hazard Networks (MHN), Hidden Extended Suppes-Bayes Causal Networks (H-ESBCNs ---PMCE---), and Disjunctive Bayesian Networks (DBN, from the OncoBN package), among others that we continue incorporating, with a single function call.
- From the fitted models, represent, graphically, the fitted models (DAGs of restrictions or matrix of hazards, as appropriate), the transition matrices and transition rate matrices (where

appropriate) between genotypes and show frequencies of genotypes sampled from the fitted models.

- Generate random EvAMs or CPMs.
- Using the shiny app, easily visualize the effects of changes in genotype composition on the fitted models by entering user-defined cross-sectional data using a GUI.

The GUI provided via the web interface allows fast construction, manipulation, and exploration of EvAM models, making it easy to gain an intuitive understanding of what these methods infer from different data sets as well as what kind of data are to be expected under these models.

Users can compare results from different methods/models, as well as experiment and understand the consequences of changes in the input data on the returned inferences. This also allows understanding how a given method performs when data have been generated under another (or its own) model.

EvAM-Tools includes extensive documentation, in the form of standard R help, clickable help and tooltips in the web application, and detailed tutorials of use.

Availability:

- Source code:
<https://github.com/rdiaz02/EvAM-Tools>.
- Publicly and freely accessible web app:
<https://www.iib.uam.es/evamtools/>
- Docker images:
<https://hub.docker.com/r/rdiaz02/evamshiny>
and
<https://hub.docker.com/r/rdiaz02/evamrstudio>

Conclusions: EvAM-Tools facilitates broader adoption of EvAMs by providing a user-friendly interface and fostering comparison of methods. This will lead to a better understanding and increased use of these methods and will encourage further methodological work and their extension to other scenarios. EvAM-Tools is thus a valuable tool for computational oncologists and more broadly to evolutionary biologists.

Evidence that human skill level is more reactive to developmental history than to genes or environment

González-Forero M¹, Gómez-Robles A²

¹Konrad Lorenz Institute For Evolution And Cognition Research, ²University College London

POSTER SESSION 1 - P01.028, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The human brain is influenced by genes, environment, and developmental history. Extensive efforts seek to identify the causes of observed variation in behaviour and disease. Moreover, it is of primary interest to predict the brain's response to influences, both at present and over our evolutionary history. Here we use a mathematical model that mechanistically recovers major aspects of human brain development and evolution to predict the response of adult skill level to point influences earlier in development. We show that adult skill level is much more reactive to changes in developmental history than to genetic, environmental, or social changes over life during the recovered evolutionary trajectory from *H. habilis* to *H.*

sapiens. This occurs despite our finding that adult skill level has evolved an increased reactivity to environmental and social change, and a decreased reactivity to genetic change, which is consistent with observation. We further show that adverse genetic and environmental conditions that would developmentally yield low adult skill level can be more than compensated by time-specific changes in the environment or by slight changes in developmental history, yielding outstanding adult skill level. Our analyses identify developmental history as having a major ability to influence adult human skill level.

GHIST: the Genomic History Inference Strategies Tournament

*POSTER SESSION 1 - **P01.017**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Evaluating population genetic inference methods is challenging due to the complexity of evolutionary histories, potential model misspecification, and unconscious biases in self-assessment. We present the Genomic History Inference Strategies Tournament (GHIST), a community-driven competition designed to independently evaluate methods for inferring evolutionary history from population genomic data. The inaugural GHIST competition featured four demographic history inference challenges of increasing complexity: a bottleneck model, a split with isolation model, a secondary contact model with demographic complexity, and an admixture model. Data were provided as error-free VCF files, and participants submitted numerical parameter estimates that were evaluated using relative root mean squared error. Approximately 60 participants competed over a five-month period, using diverse approaches. Results

revealed the current dominance of site frequency spectrum-based methods for simpler scenarios, while highlighting the advantages of flexible model-building approaches like GADMA for complex demographic histories. We discuss insights regarding evaluation strategies, including the challenge of "metagaming" behavior, and outline plans for future iterations with expanded challenge diversity, including identification of adaptive selection. GHIST aims to drive methodological innovation through transparent evaluation and community engagement, following successful models like CASP in protein structure prediction. By providing standardized benchmarks and highlighting areas for improvement, GHIST represents a significant step toward more reliable inference of evolutionary history from genomic data.

High levels of mitotic gene conversion are needed to effectively purge deleterious mutations in asexual organisms

Kopčák D^{1,2,3}, **Hartfield M**¹

¹The University Of Edinburgh, ²Institute of Science and Technology Austria, ³Okinawa Institute of Science and Technology Graduate University

*POSTER SESSION 1 - **P01.019**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Self-fertilisation and asexual reproduction are both hypothesised to lead to long-term extinction due to inefficient selection acting against deleterious mutations. Self-fertilisation can counter these effects through creating homozygous genotypes and purging deleterious mutations. Although complete asexuality lacks meiotic gene exchange, mitotic gene conversion is a mechanism for creating homozygous regions that could limit deleterious mutation accumulation in a similar manner to self-fertilisation. Here, we compare mutation accumulation in self-fertilising and facultative sexual populations subject to mitotic gene conversion, and quantify the relative efficacy of purging caused by the latter. We first show analytically that this purging is most effective with high levels of asexuality and gene conversion, and when

deleterious mutations are recessive. We further show using simulations that, when mitotic gene conversion becomes sufficiently high in obligate asexuals, there is a sudden reduction in the mutation count and a jump in homozygosity, reflecting mutation purging. However, this mechanism is not necessarily as efficient at purging compared to high levels of self-fertilisation, and elevated rates of mitotic gene conversion seem to be needed compared to empirical estimates. Hence, while mitotic gene conversion can remove recessive deleterious mutations, self-fertilisation seems to be a more effective mechanism for doing so. This talk highlights how contrasting modelling approaches (analytics and simulations) can be jointly used to tackle complex evolutionary topics.

How does ecological stability affect evolution?

King J¹, Correia A², Rebelo C³, Gardner A⁶, Nunes A^{2,5}, Fragata I^{1,5}

¹CE3C - Centre for Ecology, Evolution and Environmental Changes & CHANGE, Global Change and Sustainability Institute, Faculty of Sciences, University of Lisbon, Lisbon, Portugal, ²Department of Physics, Faculty of Sciences, University of Lisbon, Lisbon, Portugal, ³Department of Mathematics and CEMAT-Ciências, Faculty of Sciences, University of Lisbon, Lisbon, Portugal, ⁴BioSystems and Integrative Sciences Institute, Faculty of Sciences, University of Lisbon, Lisbon, Portugal, ⁵Department of Animal Biology, Faculty of Sciences, University of Lisbon, Lisbon, Portugal, ⁶School of Biology, University of St Andrews, St Andrews, Fife, United Kingdom

POSTER SESSION 1 - P01.050, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Predator-prey interactions are prevalent in many systems and are a well-known example of how eco-evolutionary dynamics may affect species interactions. While there has been a growing understanding of the effects of species interactions on evolution, we still know very little about how evolutionary trajectories may be altered by system stability, i.e. by whether new trait combinations lead to stable coexistence or population extinction. In this study, we investigate how the evolution of predator or prey traits shapes the stability of a predator-prey system, using a Rosenzweig-MacArthur predator-prey model. Using this model, we

mapped system stability to a range of different trait combinations for predator and prey, which allowed us to generate ecological fitness landscapes that identify regions of stable coexistence and predict the likelihood of different evolutionary trajectories for predator and prey. We then validated these fitness landscapes using simulations and examined how evolutionary trajectories and outcomes change when ecological stability is considered. Our findings shed light on the role of ecological stability in shaping the tempo and mode of predator-prey evolution.

How Green Is the Grass? Using Remote Sensing to Track Forage for Red Deer

Butt S¹, Macphie K¹

¹University Of Edinburgh

POSTER SESSION 1 - P01.016, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Remote sensing is a powerful tool for monitoring vegetation dynamics over time and space, but ecological applications depend on robust validation and biological interpretation. In this study, we use Normalised Difference Vegetation and Enhanced Vegetation indices (NDVI and EVI, respectively) derived from Landsat and MODIS satellite imagery to generate a high-resolution vegetation dataset for the Isle of Rum, Scotland – home to a long-studied population of free-ranging red deer (*Cervus elaphus*). Spanning the main growing season each year from 1990 to 2023, these data offer new opportunities to explore spatial and temporal trends in vegetation across Rum's heterogeneous landscape, which includes a mix of grassland (including deer forage), heath, and bog habitats.

A key strength of this system is the availability of long-term, fine-scale field data collected as part of the Isle of Rum red deer study (1972 – present). In particular, vegetation plots surveyed since the 1990s allow us to ground-truth satellite-derived greenness metrics and assess how well NDVI and EVI reflect biologically meaningful variation in plant productivity. Our analysis shows significant agreement between

remotely sensed and field-based vegetation trends, supporting the use of vegetation indices as proxies for plant growth in this system.

We also examine how vegetation dynamics vary across different habitat types within the Rum study area and demonstrate how satellite data can reveal spatial patterns that would be difficult or impossible to capture using field data alone. This spatial resolution adds a valuable new dimension to our ability to interpret environmental drivers of ecological processes, enabling future analyses that link fine-scale variation in vegetation to individual red deer life history traits — such as birth weight, overwinter survival and reproduction – and ultimately to population dynamics over time.

By integrating remote sensing data with field vegetation surveys, this work provides a case study in how to validate and apply satellite-derived vegetation indices in temperate systems. It offers a framework for using NDVI and EVI to assess spatial and temporal environmental variation in other ecological contexts where direct measurement is difficult or spatially limited.

Hues of blues: Using Comparative Genomics and Machine Learning to Uncover the Evolutionary Ecology of Color Vision in Krill

Wallberg A¹, Frazer S², Corre E³, Oakley T², Toullec J³

¹Department of Medical Biochemistry and Microbiology, Uppsala University, ²Ecology, Evolution, and Marine Biology, University of California, ³Station Biologique de Roscoff, CNRS, Sorbonne Université

POSTER SESSION 1 - **P01.035**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Do different species convergently evolve similar genetic adaptations and traits in response to shared environmental pressures? How can we use Machine Learning to advance evolutionary insights into trait evolution in non-model organisms? The present study employs a comparative analysis of krill opsin genes to explore these questions. Opsins are responsible for light sensitivity in the eyes of animals and are often adapted to the environment.

We recently assembled the 19 Gb genome of the Northern krill (*Meganyctiphanes norvegica*), a keystone macrozooplankton, and uncovered a greatly expanded opsin repertoire in this species compared to other crustaceans (Unneberg et al. 2024). A further analysis comparing Atlantic and Mediterranean populations of the species revealed evidence of adaptive divergence in allele frequencies across several opsins and numerous other genes involved in photoreception, circadian rhythm and photoperiodic regulation. These and similar findings in other marine organisms suggest that genetic adaptation to local ocean light conditions would commonly be critical in species with wide natural ranges and possibly involve convergent selection on homologous opsins and key amino acid tuning sites.

Materials and methods: Using transcriptomes from over 30 ecologically diverse krill species as models for parallel evolution and local opsin adaptation, we have identified more than 200 opsin genes. We next applied the novel OPTICS tool using machine learning models trained on the Visual Physiology Opsin Database (VPOD; Frazer et al. 2024) to predict the spectral sensitivity phenotype (λ_{max}) of each opsin. VPOD integrates experimental data from over a thousand wild-type or mutated animal opsins, including sequences and corresponding λ_{max} . OPTICS employs regression-based ML models, leveraging the DeepBreaks platform. It integrates

multiple regression algorithms, including Light Gradient Boosting Machine (LGBM), Random Forest (RF) and Extreme Gradient Boosting (XGB) to predict phenotypes from genetic sequences, while accounting for complex interactions like epistasis, and identifying critical amino acid tuning sites. These trained models show high predictive accuracy, detect known spectral tuning sites and mutation effects (including epistasis), and outperform traditional methods such as phylogenetic imputation in explanatory power, speed and error rates.

Results: We find that krill possess significantly more opsins than most other related crustaceans. ML predictions indicate a specific proliferation of middle-wavelength, blue-sensitive opsins, likely an adaptation for capturing dim light at depth, similar to deep-sea fish. Polar species express more diverse opsin repertoires than tropical species, suggesting that seasonal light variation influences opsin evolution across latitudes. We also analyze patterns of parallel and convergent spectral tuning and link predicted changes to gene duplication, selection and environment.

Conclusions: This study applies advanced ML tools to reveal novel insights into krill color vision evolution and the potential for repeatable molecular evolution among species. It highlights the benefits of combining systematic databases with ML for high-dimensional biological analysis, such as predicting molecular phenotypes of great importance to fitness and evolutionary ecology. While opsins are especially suited for such approaches due to their simple functional mechanisms, this framework is broadly applicable to other sensory proteins, such as predicting activation thresholds in thermosensory channels, offering a powerful tool for evolutionary biology and protein engineering.

Inference of dispersal and density parameters from spatial genomics data, using simulation-based machine learning methods

Camarata G^{1,2}, Rousset F¹, Leblois R², Virgoulay T^{1,2}

¹Institut des Sciences de l'Evolution de Montpellier, ²Centre de Biologie pour la Gestion des Populations

POSTER SESSION 1 - P01.044, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

During my PhD, I contribute to the development of indirect demographic inference methods. The aim is to provide the tools necessary to evaluate recent and local population history (mainly density and dispersal in the last dozens generations) using spatial and genomic data. This would inform conservation and management strategies while being less costly than approaches such as mark-recapture.

To achieve this goal, we use a simulation-based approach. Our method links the spatialised simulator GSpace (Virgoulay et al., 2021), the summary statistics calculating library GSumStat and the summary

likelihood statistical framework implemented in the infusion R package (Rousset et al., 2017).

GSpace implements both coalescent and forward time models of isolation by distance. GSumStat allows efficient computation of a wide variety of commonly used summary statistics. Infusion uses an iterative approach to infer joint distributions of likelihood of multiple parameters, by leveraging tools such as random forest machine-learning method and multivariate Gaussian mixture models.

Inferring the history of gene copy number evolution

Otto M¹, **Wiehe T**

¹University Of Cologne

POSTER SESSION 1 - **P01.040**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Gene duplication plays a crucial role in the adaptive evolution and diversification of organisms by creating extra copies of genes that can evolve new functions while preserving the original. Duplicated genes can become fixed in populations or appear as copy number variants. However, inferring and dating these duplication events from present-day data is challenging, as gene copy count distributions could result from either a few ancient duplication events or many recent ones. Here, we introduce a novel model for inferring gene copy number evolution, which describes gene duplication and their evolution over time through a

random walk on a graph. We apply this model to the NB-ARC domain counts of NLR genes in *A.thaliana*, reconstructing the most likely 'duplication path' in the ancestral duplication graph to estimate duplication rates and date those gene duplication events. Using these estimates, we perform structured coalescent simulations that account for mutations and calculate key population genetic statistics, such as Tajima's D. Our findings indicate that naive sequence-based analyses of gene copy numbers may lead to misinterpretations of evolutionary history and underline the importance of including a duplication model.

Investigating the Maintenance of Alternative Reproductive Tactics in *Tetranychus urticae* males

Freerks K¹, Egas M¹

¹Groningen Institute for Evolutionary Life Sciences

POSTER SESSION 1 - P01.036, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Rapid environmental change necessitates predictive models of ecological and evolutionary responses, which can be effectively tested in species that display polymorphisms. Our project investigates the eco-evolutionary dynamics of male two-spotted spider mites (*Tetranychus urticae*), which exhibit alternative reproductive tactics (ARTs): fighter and sneaker tactics. Unlike other species where ARTs are linked to morphological differences, these tactics are behaviourally distinct yet morphologically identical.

Materials and Methods: To understand how these tactics are maintained and whether they represent fixed or flexible strategies, we employ advanced behaviour quantification tools to assess the behavioural phenotypes of individual males over time. High-resolution video recordings are used to capture male interactions under controlled conditions. Postural data are extracted using DeepLabCut, enabling individual

identification and tracking across extended behavioural observations.

Results: We successfully trained a mite posture detection model capable of accurately identifying and tracking individuals across varied lighting conditions and arena setups. This system provides a reliable foundation for future quantification of behavioural variation and tactic expression.

Conclusions: This work establishes the methodological groundwork for analysing the flexibility of alternative reproductive tactics in *T. urticae*. With individual identification in place, we are now positioned to test how ecological and intrinsic factors such as age, mating status, predation risk, and sex ratio may influence ART expression, contributing to a better understanding of behavioural plasticity and eco-evolutionary feedbacks in polymorphic mating systems.

Modelling the evolution of division of labour in clonal groups

Shillcock G¹, West S¹, Grafen A¹

¹Department of Biology

POSTER SESSION 1 - P01.051, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Division of labour, when cooperating individuals specialise in different tasks, occurs at every scale of biological organisation, from genes to complex animal societies. It is therefore crucial for us to understand the conditions which promote division of labour. Part of the complexity is that division of labour can confer fitness benefits for various reasons, in different biological cases. Previous theoretical research has often focused on only one of these reasons or specific types of tasks. There is a need for a theory that unifies different cases.

We model how a clonal group evolves to perform the various tasks contributing to its fitness. This framework is designed to be as general as possible by accommodating clonal groups of any size, performing any type and number of tasks. Our results apply to groups of genes, cells, organisms, or any

other evolutionary individuals. Our model shows there are at least three reasons why division of labour can be favoured by natural selection: (1) particular individuals may be predisposed to particular tasks, for example when individuals have differing access to resources; (2) focusing resources may increase individual efficiency, for example when task products do not mix well or tasks require up-front costs; and (3) specialists may contribute disproportionately to the group's aggregate performance, for example in cooperative defence. Group size is also shown to generally promote division of labour.

Our model allows us to categorise different forms of division of labour, according to certain biological scenarios. This can be used as a predictive tool for experimentalists to explain when division of labour does and doesn't occur.

Predator decision shape dynamics and stability of mimicry systems.

Sun Y^{1,2}, Ke P²

¹Johannes Gutenberg University Of Mainz, ²Institute of Ecology and Evolutionary Biology National Taiwan University

POSTER SESSION 1 - P01.025, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Mimicry is a widespread anti-predator strategy where a prey species (the mimic) resembles an unprofitable species (the model) to deceive predators. Despite theoretical expectations for perfect mimicry, imperfect resemblances are common in nature. Here, we study the population dynamics and stability of both single- and multi-mimicry systems, focusing on the influence of varying predator recognition abilities. Using a theoretical framework that integrates optimal foraging theory, signal detection theory, abundance dependent recognition, and population dynamic, we demonstrate that intermediate mimic--model similarity stabilizes dynamics and promotes mimic abundance, thereby challenging past expectations for perfect mimicry. This stabilizing effect persists even when predators dynamically adjust their

recognition based on the mimic to model abundance ratio. Furthermore, this beneficial effect of imperfect mimicry persisted when we extended the framework to a multi-mimicry system involving both Batesian and Müllerian mimics. Batesian and Müllerian mimics confer different levels of protection to the system depending on the degrees of resemblance: Batesian mimics offer protection under intermediate similarity, while Müllerian mimics provide consistent protection under both intermediate or high similarity. Overall, our study offers novel insights into the prevalence of imperfect mimicry in nature --- it can represent an ecologically stable anti-predator strategy across a wide range of predator recognition abilities, and mimicry systems.

Quantifying camouflage evolution: digital phenotyping and macroevolutionary modelling in Neotropical butterflies

Suzuki T¹, Tomita S², Sezutsu H²

¹Juntendo University Graduate School Of Medicine, ²National Agriculture and Food Research Organization

POSTER SESSION 1 - P01.033, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Recent advances in image analysis, morphological theory, and phylogenetic comparative methods are transforming how we study the evolution of complex traits in ecological contexts. These tools now enable us to quantify phenotypic complexity, decompose structural pattern components, and reconstruct the evolutionary sequences of traits across phylogenies.

Here, we apply these integrative methods to investigate the origin of complex cryptic patterns in butterflies and their interplay with behavioural innovation. We focus on lichen crypsis in Neotropical butterflies of the genus *Hamadryas*, which rest with wings open on lichen-covered bark, displaying intricate dorsal wing patterns that closely mimic the background's texture and colour. This open-wing resting posture—unusual for butterflies and more typical of moths—visually aligns the pattern with the background and likely enhances camouflage. This system provides an ideal context to assess how behavioural and morphological traits may have co-evolved in response to visually complex environments. Our study integrates three analytical components. First, we used high-resolution image analysis to quantify dorsal wing pattern complexity in 25 species of *Biblidinae*, employing edge-density metrics and spatial frequency analysis. We show that lichen-mimetic species exhibit significantly higher pattern complexity than their non-mimetic relatives. Second, we performed morphological decomposition based on the nymphalid ground plan to identify the

structural origins of this complexity. Lichen-mimetic species were found to modify conserved pattern elements and incorporate novel components, suggesting a layered evolutionary process. Third, we combined behavioural observations with phylogenetic comparative methods to reconstruct the evolutionary sequence of resting posture and pattern complexity. Our results indicate that the open-wing posture evolved prior to the emergence of complex lichen-like patterning, supporting a behaviour-first evolutionary pathway.

Together, these findings provide empirical evidence for the behaviour-first hypothesis—the idea that behavioural innovations can precede and facilitate morphological adaptation by reshaping the selective environment. In this case, a shift in resting posture appears to have enabled the exploitation of visually complex microhabitats, setting the stage for the subsequent evolution of cryptic wing patterning.

Our study demonstrates how the integration of digital phenotyping, morphological theory, and phylogenetic inference can test macroevolutionary hypotheses about trait interaction. It also exemplifies how classical natural history systems, such as butterfly mimicry, can be revisited using cutting-edge computational tools to uncover the dynamics of behavioural and morphological co-evolution. In doing so, we contribute to the broader effort of linking technological innovation with theory-driven questions in evolutionary ecology

Quantifying the effects of antibiotic resistance and within-host competition on strain fitness in *Streptococcus pneumoniae*

Krishna A¹, Tonkin-Hill G², Morel-Journel T³, Bentley S⁴, Turner P⁵, Blanquart F⁶, Lehtinen S^{1,7}

¹ETH Zurich, ²Peter Doherty Institute for Infection and Immunity, Australia, ³Université Sorbonne Paris Nord, ⁴Wellcome Sanger Institute, ⁵Centre for Tropical Medicine and Global Health, Nuffield Department of Medicine, University of Oxford, ⁶Center for Interdisciplinary Research in Biology, CNRS, Collège de France, ⁷Department of Computational Biology, University of Lausanne

POSTER SESSION 1 - P01.041, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In multi-strain pathogens like *Streptococcus pneumoniae*, competition between strains shapes the dynamics of traits like virulence or antibiotic resistance. In pneumococcal epidemiology, this competition is traditionally conceptualised at the between-host scale - i.e. for hosts to colonise. However, because co-colonisation is common, strains also compete at the within-host scale. A growing body of theoretical work is highlighting the impact within-host competition has on dynamics at the between host scale. Yet, there is little empirical work on within-host competition. This poses a fundamental problem for our understanding of e.g. antibiotic resistance dynamics.

In this work, we address this problem using statistical analysis of the largest-to-date longitudinal dataset of pneumococcal carriage. We perform survival analyses on this dataset to quantify how within-host competition affects the rates of clearance

and establishment of pneumococcal strains. We find that the presence of a within-host competitor is associated with a 33% increase in clearance and a 54% reduction in establishment. Priority effects and serotype differences partially predict the outcomes of this within-host competition. Further, we quantify the effects of antibiotic resistance on between- and within-host components of fitness. Antibiotic consumption is associated with increased clearance rate for both susceptible and resistant strains, albeit to a higher extent in susceptible strains. In the absence of antibiotics, we find some evidence that resistance is associated with increased susceptibility to within-host competition, suggesting a fitness cost of resistance. Overall, our work provides quantitative insights into pneumococcal competition across scales and the role of this competition in shaping pneumococcal epidemiology.

Quantitative approaches reveal that viral cheats are highly abundant and form species-specific communities in natural infections of H5N1 avian influenza.

Leeks A¹, Routh A², Díaz-Muñoz S³

¹Department Of Zoology, UBC, ²Scripps Institute, ³University of California at Davis

POSTER SESSION 1 - **P01.038**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Viral infections are social processes. To successfully replicate inside infected cells, viruses must produce shared gene products, that can be used by multiple viral genomes within the same cell, and hence act as public goods. As a result, viral cheats can emerge, a type of molecular parasite formed by large deletions, which spread by exploiting public goods encoded by full-length viruses. Cheats exist across the viral universe, arise frequently in laboratory infections, and reflect the emergence of evolutionary conflict at the molecular level. If cheats are also common in natural viral infections, they could play a key role in viral population dynamics, pathogenesis, and adaptation.

Here, we report the widespread abundance of viral cheats across diverse species infected by the recently emerged strain of H5N1 avian influenza. Within thousands of newly available deep-sequencing datasets, we use bioinformatic tools to find that the majority of infected animals contain viral cheats at detectable frequencies. Strikingly, in more than one in four animal infections, cheats reach a relative abundance greater than 50%, indicating that they are the majority variant within that population.

We then interrogate this dataset using mathematical and statistical tools drawn from evolution and ecology. We ask three key questions. Firstly, we use statistical tools

from community ecology to show that viral cheats form distinct communities within each infected host, such that different host species are characterised by different viral cheat sequences becoming highly abundant. This indicates that separate mutational and selective forces shape the emergence and evolution of cheating across host species. Secondly, we use birth-death models to quantify the strength of selection for cheating required to generate the patterns of cheat diversity and abundance that we see. This reveals that for some host species, viral cheats could be driving cooperator viruses extinct over the course of an infection, in a way that is analogous to the emergence of cancer in multicellular organisms. Thirdly, we test for a genetic basis of susceptibility to cheating, finding that cheat abundance is phylogenetically conserved. This indicates that standing genetic variation exists for susceptibility to viral cheating within circulating H5N1 lineages, suggesting conflicting selection pressures at the within- and between-host level.

Overall, our findings suggest that: cheats are highly abundant in natural influenza infections of diverse animal species; new large viral sequencing datasets call for new mathematical and statistical approaches; the resulting evolutionary insights reveal the previously unseen social complexity of viral infections.

SAI: A tool for Statistics for Adaptive Introgression

Kuhlwilm M¹, Hackl J¹, Chen S¹, Huang X¹

¹University Of Vienna

POSTER SESSION 1 - P01.039, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Adaptive introgression is an important evolutionary process, for which an approach has been developed based on summary statistics, such as the number of uniquely shared sites and the quantile of derived allele statistic. However, no accessible implementation has been available, limiting reproducibility and methodological clarity. Here, we present SAI, a package for computing these in a flexible and robust manner, which allows an easy application to different datasets. We demonstrate using the 1000 Genomes Project data, that SAI can replicate previously reported candidate regions based on these statistics, and identify additional ones, including a region

detected using a deep learning method. Furthermore, we show that SAI can be applied to non-human diversity datasets to detect adaptive introgression. We investigated bonobo introgression into central chimpanzees, providing candidate regions that might have been beneficial in chimpanzees after gene flow. Interestingly, one candidate region was also found at high frequency in modern Papuans and assigned to Denisovan adaptive introgression. Such co-occurrence suggests that similar genes might have been beneficial after introgression in different species.

Semi-supervised selection target detection with positive-unlabeled learning

Arnab S¹, Campelo dos Santos A¹, DeGiorgio M¹

¹Florida Atlantic University

POSTER SESSION 1 – P01.030, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Identifying genomic regions shaped by natural selection is a central goal in evolutionary genomics. Existing machine learning methods for this task are typically trained using simulated genomic data labeled according to specific evolutionary scenarios. While effective in controlled settings, these models are limited by their reliance on explicit class labels. They can only detect the specific processes they were trained to recognize, making it difficult to interpret predictions for regions influenced by other evolutionary forces. This limitation is especially problematic when analyzing empirical genomes shaped by a mixture of adaptive, demographic, and ecological factors. One-vs.-rest strategies offer a potential alternative, but suffer from the inherent complexity of modeling all other evolutionary and demographic processes as a catch-all "rest" class. Here, we explore positive-unlabeled learning as a more flexible framework for detection of adaptive events. Positive-unlabeled learning is a semi-supervised approach that permits identification of samples of a target class using only positive labels and an unlabeled background, without requiring explicit modeling of negative samples. To assess the utility of this approach, we focus on a binary

classification setting for detecting selective sweeps (positive samples) arising from positive natural selection against a mixed background composed of both unlabeled sweeps and neutrally-evolving regions. To accomplish this goal, we introduce PULSe, a method that employs only a set of labeled sweep observations for training while treating all remaining data as unlabeled. By avoiding assumptions about the composition of the background, PULSe enables robust sweep discovery in realistic genomic landscapes. We systematically evaluate its performance across a range of demographic, adaptive, ecological, and confounding contexts, including domain shift arising from misspecified demographic models, and find that PULSe delivers high performance and generalizability. To demonstrate a practical application of PULSe, we analyzed European human genomes, treating the empirical genome as the unlabeled set, and recapitulating several previously-identified sweep candidates. Our results show that PULSe provides a powerful, and versatile alternative for detecting adaptive regions, with the potential to generalize across a range of genomic landscapes, including non-model organisms.

Species trait data imputation via deep learning

Turner M¹

¹University Of Aberdeen

POSTER SESSION 1 – P01.026, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Species traits are the morphological, demographic, physiological, phenological, and genetic features of a given species, and are used in studies such as biodiversity forecasting, parameterising process-based models, and investigating species evolutionary histories, as well as in conservation projects. These data often display high degrees of missingness, and as such effective data handling techniques are essential to maximize data availability. One such approach is data imputation, in which a most probable value is determined for missing data.

Current approaches for imputing missing species trait data often focus on applying statistical and simple machine learning approaches such as random forest. Deep

learning approaches offer a potentially powerful alternative to these traditional methods due to their capacity to ‘understand’ complex relationships within large datasets.

Here, we present our work on the development of deep neural network models for imputing missing species trait data, including the training and application of deep neural networks and foundational models. We also fine-tune a pre-trained foundational prior fitted network for the same task. These models have the potential to provide significant performance improvements over conventional trait data imputation approaches under a variety of missingness data scenarios, providing researchers with more robust trait datasets.

The avian colourscape and its uncertain future

MacDonald R¹

¹University Of Sheffield

POSTER SESSION 1 – P01.029, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The profusion of animal colour – from birds to butterflies – is one of the most striking aspects of biodiversity, and something we as humans intrinsically value. But is this diversity under threat as our environment changes and species face extinction? One barrier to understanding and mitigating this impact is the difficulty in quantifying diversity in holistic colour pattern phenotype, a notoriously complex trait. Here, I explore our

work leveraging recent advances in machine-learning-based computer vision techniques to quantify current and future diversity in colouration in birds, a famously colourful group of animals. We find that avian colour pattern diversity may be at risk of homogenisation from anthropogenic extinctions, with the loss of threatened species leading to disproportionate reductions in colour diversity.

The friendship paradox and social structuring in animal societies

Newman E¹, Knowles S¹, Firth J^{1,2}

¹Department Of Biology, University of Oxford, ²Faculty of Biological Sciences, University of Leeds

POSTER SESSION 1 – **P01.048**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: A population's social structure, or 'social network', shapes various biological processes, including the spread of disease, information, and behaviour. How social structure arises governs how these contagions spread. One network phenomenon of interest is the 'friendship paradox' – where on average an individual's connections have more connections than they do. It is a way of measuring relationship disparity within and across a social network, and thus how social structuring across species leads to asymmetric social experiences. By quantifying this relationship disparity across networks, we suggest a new metric to use to understand the trade-off behind social interactions. Understanding what network and biological features are associated with this disparity is important for uncovering the evolutionary pressures shaping social behaviour, yet there is currently little understanding of how it varies across real-world social networks, and what biological or network properties can exaggerate it or diminish it.

Materials and methods: We analysed 399 wild animal social networks to consider how the strength of the friendship paradox varies

with intrinsic network characteristics and biological attributes. We then applied a null modelling approach to examine whether the friendship paradox was accentuated more than expected given network structural features.

Results: Several key network structures and biological features predicted the strength of the friendship paradox, with larger and denser networks generally exhibiting a weaker friendship paradox, and mammals and birds showing a stronger relationship disparity. We found that mammalian and reptilian networks had less disparity than expected from their network structure.

Conclusions: These findings highlight how application of network theory can reveal insights into underlying principles of social structure. This study demonstrates how applying computational and network-theoretic tools in a comparative study can uncover general patterns in social structuring across species. It highlights the potential of network-based modelling to bridge behavioural ecology and evolutionary theory.

The Inference Challenge: Regularization Methods Across Computational Paradigms in Evolutionary Ecology

Yates L¹, Haliwell B¹

¹University Of Tasmania

POSTER SESSION 1 – P01.037, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In the era of big data and machine learning, evolutionary ecologists face a fundamental tension between predictive power and causal inference. This methodological work explores this inferential challenge through regularization strategies across both classical statistical and machine learning approaches applied to multivariate trait data in comparative phylogenetics and population genetics.

We compare regularization philosophies for detecting sparse signals in correlation structures: traditional Bayesian priors, sparsity-inducing regularization (horseshoe and adaptive lasso), and dimension-reduction techniques. Using Stan, we implement these with optimized likelihood calculations for tree-based data structures. We also explore neural network architectures that incorporate structured biological dependencies through appropriate distance metrics.

These approaches highlight contrasting validation philosophies: classical statistical methods offer rigorous parameter uncertainty quantification using posterior

distributions or confidence intervals as the foundation for inference, while machine learning primarily validates through predictive performance, with limited tools for assessing uncertainty in internal parameters or post-hoc explanations. The dual challenge across computational paradigms is managing model complexity: insufficiently regularized models risk hallucinating spurious patterns, while excessive regularization can eliminate genuinely sparse but important signals—both undermining valid inference in complex evolutionary systems.

Our preliminary results based on simulation studies in the classical domain suggest that targeted regularization approaches like horseshoe priors show promise in recovering sparse (partial) correlations in multivariate tree-structured trait data by adaptively determining where complexity is needed. Using simulated and real data sets, our results demonstrate how different regularization strategies represent inherent trade-offs between interpretability, computational efficiency, and inferential validity in complex evolutionary models.

The Power of Three: Enhancing Arthropod–Plant Interaction Monitoring with Citizen Science, Expert Taxonomic Criteria, and Computer Vision Models

Pérez Lorenzo I^{1,2}, Platanía L¹, Palazzesi L³, Pellicer J¹, Hidalgo O¹

¹Institut Botànic de Barcelona, ²Facultat de Farmàcia i Ciències de l'Alimentació, Universitat de Barcelona, ³MUSEO ARGENTINO DE CIENCIAS NATURALES "BERNARDINO RIVADAVIA"

POSTER SESSION 1 – P01.018, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The coevolution between flowering plants and their visitors has charmed evolutionary biologists for centuries. Yet, data on reproductive biology remain sparse for most plant families—especially those considered to have generalist pollination strategies, such as the Asteraceae, one of the most speciose angiosperm families. Here, we present a pipeline for processing video-based floral visitor data, built around a custom YOLO (You Only Look Once) object classification model. This approach combines citizen science, expert taxonomic input from botanists and entomologists, and computer vision to automate and scale up the monitoring of plant-arthropod interactions. Pipeline Overview: Model Preparation—(i) We compiled a species list of arthropods from the Pyrenees based on two curated iNaturalist projects focused on Asteraceae interactions, yielding over 7,000 observations (covering ~600 arthropod and 150 Asteraceae species). (ii) We then assembled a dataset of 399,460 images across 330 arthropod species sourced from GBIF (Global Biodiversity Information Facility), excluding taxa with insufficient image data. (iii) This dataset was used to train and validate a custom YOLO model, achieving an 81% precision for the top

predicted class and 90% for the top five predictions. (iv) To improve classification reliability, we developed a performance index combining prediction confidence and consistency across the top predictions. Video Analysis—(v) We processed over 800 hours of video from ten Asteraceae species in the Pyrenees, extracting one frame per second. (vi) The YOLO model was applied to each frame, generating summary tables of interaction times, predicted taxa, and performance scores. Key frames were sorted into folders for expert review. Model Validation—(vii) An entomologist evaluated a subset of predictions and conducted direct video assessments to identify potential biases—such as false positives, overlooked species that were not part of the training dataset, or taxa undetected in the automated analysis. This study highlights the promise of computer vision in overcoming long-standing data limitations in the study of plant-arthropod interactions. While challenges remain—particularly in generating high-quality training data and ensuring accurate species recognition—our results show how citizen science and expert knowledge can be effectively combined to advance ecological research at scale.

The Role of Robustness in Shaping Metabolic Network Evolution Across Species

Monge Lorenzo J¹, Stelling J¹

¹Department of Biosystems Science and Engineering (D-BSSE), ETH Zurich

POSTER SESSION 1 – P01.042, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biological systems face the dual challenge of maintaining stable function in the face of perturbations while also adapting to new environments and evolutionary pressures. This balance between robustness and evolvability is particularly evident in metabolic networks, which must resist disruption yet remain capable of innovation. We propose a framework to investigate how metabolic networks navigate this trade-off by combining systems biology approaches with evolutionary analysis.

Specifically, and in contrast to prior work, we assess robustness as well as function similarity of metabolic networks using structural sensitivity analysis applied to genome-scale metabolic models. Structural sensitivities identify reactions whose perturbation—such as changes in enzyme activity or gene expression—has significant effects on overall network function. By quantifying the sensitivity of individual reactions, and the correlations of sensitivities between networks of different species, we can determine which parts of the networks are most functionally similar and most critical to maintaining stability.

In a first step to explore the evolutionary consequences of this sensitivity, we propose comparing the network's sensitivity to internal (mutational) versus external (environmental) perturbations to assess whether robustness has evolved more strongly in response to one type of challenge.

This includes examining whether evolutionary rates of enzymes differ depending on the type of perturbation to which they are most sensitive, helping to identify dominant sources of selective pressure. In terms of sensitivities, we find slightly higher values for the perturbation of exchange reactions. When we use sensitivity profiles to reconstruct phylogenetic trees—based either on internal or external perturbations—we obtain different topologies, indicating that the type of perturbation considered influences the inferred evolutionary relationships. We will relate this to mutation rates (dN/dS) to explore how selective pressures have shaped these trends.

Our framework aims to shed light on the fundamental principles governing how metabolic systems remain both stable and adaptable under evolutionary pressure by assessing network function via structural sensitivities, without the need for detailed (evolutionary) models. We consider our first results regarding differential sensitivity to internal and external perturbations – and their impact on phylogenetic inference – as promising in this direction. In the future, to investigate other aspects of long-term evolutionary dynamics, for example, we will examine the fate of duplicated metabolic genes, considering that gene duplication is a major source of innovation.

When barriers break: the probabilistic assembly of pathogen's host-range and the percolation of epidemics

Bolanho Mendes P^{1,2}, Andreazzi C^{1,3}

¹Laboratório de Biologia e Parasitologia de Mamíferos Silvestres Reservatórios, Instituto Oswaldo Cruz, Fundação Oswaldo Cruz, ²Biological Interactions, Universidade Federal do Paraná, ³Departamento de Biodiversidad, Ecología y Evolución, Universidad Complutense de Madrid

POSTER SESSION 1 – P01.047, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Understanding how changes in pathogen host range influence disease spread is essential for anticipating large-scale outbreaks. Percolation theory, traditionally used in physics, has recently been applied to ecological networks to explain sudden transitions from localized outbreaks to widespread epidemics. However, little attention has been given to how evolutionary changes in pathogen composition interact with the host contact network to trigger percolation. Here, we integrate evolutionary and ecological theory to investigate how percolation emerges from the evolutionary dynamics of a pathogen's host range.

Materials and Methods: We developed a probabilistic model of pathogen evolution and transmission across a weighted, directed host-contact network. Each node represents a host species population of 100 individuals. Edge weights define the probability of contact between nodes. Pathogen strains are characterized by vectors of host-specific capacities determining replication and infection success. At each time step, infected individuals release propagules, which disperse through the network according to normalized edge weights, forming the ecological opportunity for spread. For each potential host, the number of encounters with propagules is drawn from a binomial distribution, based on propagule load and contact probability. A second binomial process determines which encounters result in infections, based on the pathogen's capacity in that host. Within hosts, strains compete through deterministic exclusion: only the most competitive strain (with highest capacity) persists. Evolution occurs through mutations during infection: new strains arise via random mutations in capacity; capacities to other host species are influenced by trait correlations, capturing trade-offs and pleiotropic constraints. This framework captures both ecological transmission and evolutionary diversification, accounting for phylogenetic conservatism, host heterogeneity, and network structure.

We ran a total of 96 simulations across multiple contact networks, tracking the emergence of new variants, their transmission, and the resulting dynamics of spread and percolation.

Results: Across simulations, percolation consistently followed host-range expansion into new network modules. This suggests modular boundaries act as ecological barriers, and that percolation arises through a synergistic build-up of propagule pressure across modules, rather than within a single compartment.

Percolation was typically preceded by infection of a high-capacity host in another module. These key hosts act as evolutionary amplifiers, enhancing persistence and increasing the chances of cross-module transmission.

Percolation consistently occurred only after the total number of infected individuals reached a critical abundance threshold, which remained relatively stable across network structures. This suggests a minimum infection load is required to trigger percolation, reflecting a fundamental constraint in transmission dynamics.

Finally, percolating variants most often emerged in their ancestral (reservoir) host, likely due to a combination of higher evolutionary capacity and sustained transmission amplification in that host.

Conclusions: Our results show that epidemic transitions are shaped by the interaction between evolving host range, modular host community structure, host-specific capacities, and temporal variation in transmission. Unlike traditional models based on stochastic transitions between network states, our framework captures the continuous spread of propagules governed by biologically grounded parameters. This propagation-based approach offers a mechanistic and evolutionary perspective on how pathogens overcome barriers to colonize new hosts. By integrating evolution into network epidemiology, this study provides a generalizable framework for predicting pathogen emergence and identifying the ecological conditions driving epidemic spillovers.

Eco-evolutionary dynamics of finite populations from first principles and the noise-induced reversal of natural selection

Bhat S^{1,2}, Guttal V²

¹Johannes Gutenberg University, ²Centre for Ecological Sciences, Indian Institute of Science

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

While we understand evolution in infinitely large populations in a remarkably general manner through frameworks such as the Price equation, finite populations are considerably more complex. Standard models in population genetics, such as the Wright-Fisher or Moran model, assume the total population size is either strictly constant or varying according to externally imposed 'top-down' rules, thus neglecting ecological dynamics and density-dependent demographic effects. In this talk, I will show how modern tools from stochastic calculus and Markov chains can be used to analytically derive equations for the eco-evolutionary dynamics of finite populations from demographic first principles. Our equations generalize and extend well-known descriptions of evolution, such as the replicator equation, Price equation, and Fisher's fundamental theorem, to finite populations of non-constant size. Our framework also reveals how stochasticity in finite populations can predictably bias evolutionary trajectories to favour certain traits, a phenomenon we call "noise-induced biasing". We show that noise-induced biasing acts through two distinct mechanisms, the "direct" and "indirect" mechanisms. While the direct mechanism can be identified with classic bet-hedging theory, the indirect mechanism is a more subtle consequence of frequency- and density-dependent demographic stochasticity. Our equations reveal that noise-induced biasing may lead to evolution proceeding in a direction opposite to that predicted by selection-mutation-drift balance alone in finite populations, helping explain several recent studies showing counter-intuitive effects of stochasticity on evolutionary dynamics.

I will also sketch how one can carry out an analogous derivation for populations bearing quantitative traits. Modelling the complete dynamics of quantitative trait distributions in finite populations is mathematically challenging since infinitely many distinct trait variants may

arise in such populations. I will show how tools from stochastic field theory and infinite-dimensional stochastic analysis can be used to derive the complete dynamics of the distribution of a quantitative trait in a finite population of non-constant size from first principles. The resulting equations extend classic results from quantitative genetics, such as the Crow-Kimura equation and Lande's gradient equation, to the stochastic, dynamic setting relevant to finite populations. On the mathematics side, the work on quantitative traits also introduces new mathematical techniques for modelling stochastic quantitative trait evolution using stochastic partial differential equations (SPDEs). These new mathematical techniques complement the existing standard approach in the literature, thus expanding the theoretical toolbox to model quantitative traits in finite populations. As an application, we will see how the SPDE approach allows us to use Fourier techniques to study adaptive diversification in finite populations.

Several theorists have called for a reformulation of eco-evolutionary dynamics from the demographic first principles of birth and death rates because such a formulation is more fundamental and 'all roads to fitness lead through demography'. Our work provides a starting point for such a reformulation, using modern mathematical tools to generalise some fundamental equations of eco-evolutionary theory. The idea of noise-induced biasing also conceptually unifies a considerable number of existing studies under a single theoretical framework.

How does species diversity affect ecological stability?

Liu M¹, Piskovsky V¹, Tomanek I¹, Brown D¹, Foster K¹

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

Background: The diversity-stability relationship remains a foundational yet contentious topic in evolutionary ecology. Resolving how species diversity impacts ecological stability is critical for understanding ecosystem resilience in a rapidly changing world.

Materials and Methods: We developed a generalized mathematical framework that integrates canonical ecological models—including generalized Lotka-Volterra, consumer-resource, and sublinear models—by explicitly incorporating nonlinear growth functions defined by density-dependent per capita growth rates. We systematically examined how different functional forms of the growth function influence stability outcomes across diverse parameter spaces.

Results: Our theoretical analysis revealed that the diversity-stability relationship

depends fundamentally on the shape of the growth function. Specifically, we demonstrated that increasing species diversity always destabilizes ecological communities, unless (1) intraspecific interactions exhibit specific decelerating nonlinear density regulation, and (2) interspecific interactions follow linear or accelerating regulations. Empirical analyses on macroecological and microbial data further support the dominance of destabilizing patterns.

Conclusions: This study demonstrates how advanced mathematical modeling and computational methods can reconcile longstanding debates in ecological theory. Our results highlight critical conditions under which species diversity can enhance stability, offering theoretical insights crucial for understanding ecosystem resilience.

Inference of ecological and life-history traits evolution from genomic and epigenomic polymorphism data.

Tellier A¹, Ramesh A, Sellinger T, Korfmann K, Abu Awad D, Metzger L, Anderson M

¹Technical University of Munich

MEETING ROOM 129+130, August 18, 2025, 10:30 AM - 12:30 PM

While most population genetics inference methods using full-genome data can be, in principle, applied to all species, the underlying assumptions of classic models of population genetics are often sexual reproduction in each generation and non-overlapping generations. However, in many plants, invertebrates, fungi and other taxa, those assumptions are often violated due to different ecological and life history traits, such as self-fertilization, long term dormant structures (seed or egg-banking) or large variance in offspring production. Moreover, these life-history traits do evolve themselves in response to changing climate and ecology of the species. In return life-history traits do determine species genetic diversity and evolutionary potential to adapt to biotic and abiotic changes. Yet, the evolution of such life-history traits has been chiefly studied using phylogenies over macroevolutionary time scales, preventing to study recent trait transitions and the underpinning neutral and selective mechanisms. Furthermore, the resolution of past population genetics inference decreases when there is a lack of SNPs in the data, decreasing the resolution of inference in recent times, especially recent effects of climate change. Technological advances allow now to use genomes and epigenomes (methylation data) for model and non-model species to

decipher the evolutionary processes driving ecological adaptations.

Building on adapted coalescent models, we have developed novel inference methods which aims at estimating transitions in life-history traits using full genome polymorphism data. We developed Sequential Markovian Coalescent (SMC), Approximate Bayesian Computation (ABC) as well as Deep Learning (DL based on large language models) methods to 1) infer transitions in seed banking / dormancy or selfing rates in time, and 2) integrate epigenetic (methylation) markers to improve the inference of recent events. We provide here an overview of the statistical power and robustness of these various methods in estimating and disentangling between demographic events and trait transitions. We then explicit the footprints of these trait transitions in the genome wide polymorphism data and how to detect them using statistics such as transition matrices summarizing times to the most recent common ancestor. We explicit the respective contributions of SMC, ABC and DL methods to our understanding of the heterogeneity in genomic footprints of trait transitions. We finally highlight the novel insights gained with DL methods to decipher the evolutionary processes driving the evolution of ecological/life-history traits.

Neural ODEs for understanding population dynamics

Patel M¹

¹University Of Hull

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

Ordinary Differential Equations (ODE) are a widely used tool in understanding dynamics of systems. In Evolutionary-ecology they are used in population dynamic modelling and most relevantly for eco-evolutionary processes in adaptive dynamics approaches. Neural Ordinary Differential Equations (NODEs or Neural ODEs) apply the concept of neural operators to differential equations to learn the differential equations of a system from data. This is a Data driven approach to understanding the dynamics of a system. In this talk I hope to give anyone familiar with the basic concept of an ODE an intuition for what a neural ODE is doing and how to use them to unravel the ecological dynamics of a system. I will present some applications of neural ODEs to long term time series data of species from the Global

Population Dynamics Dataset. And give a proof of concept of how they can be used with existing datasets to better understand complex ecological dynamics. This is still a relatively young field and I believe there are many challenges to implementing neural ODEs robustly. My hope is this talk will widen interest in using neural ODE and spark further discussion in the literature on how to use neural ODEs to best effect.

The talk will give a simple introduction to how neural networks and ODEs can be integrated. How training is done including common packages in Python and Julia to do this training. And some explorations of how to recover biological insights from the trained neural networks so they are not being used as simple black boxes.

Neural posterior estimation for high-dimensional simulation data from complex ecological and population genetic models

Min J², **Ning Y**¹, Pope N², Baumdicker F¹, Kern A²

¹University Of Tübingen, ²University of Oregon

MEETING ROOM 129+130, August 18, 2025, 10:30 AM - 12:30 PM

Quantifying the evolutionary forces that shape natural populations is a key challenge in evolutionary ecology, where accurate inference improves our understanding of eco-evolutionary dynamics and local adaptations. Simulation-based inference has shown great potential and become increasingly useful in this field because they accommodate biologically realistic models when likelihoods are intractable. Approximate Bayesian Computation (ABC) is a widely used simulation-based inference method, but comes with substantial computational expense and struggles to fit models to high-dimensional summaries of the data now routinely collected in ecological studies. In contrast, supervised Machine Learning (ML) techniques are capable to handle such high-dimensional data. However, ML methods generally do not yield Bayesian uncertainty estimates of the quantities they predict. Here, we present neural posterior estimation (NPE), a deep-learning framework that combines the best facets of ABC with the efficiency of supervised machine learning. By training

neural density estimators on simulated data, NPE directly approximates the full posterior distribution of model parameters.

Benchmarking across a variety of population genetic tasks shows that the neural posterior estimators yield posterior distributions with high accuracy and better efficiency than ABC or parametric bootstrapping. We use the 2 epoch demographic model of *Arabidopsis thaliana* to estimate the timing and magnitude of a bottleneck event. We also demonstrate that incorporating linkage-based statistics alongside classical site frequency spectra improves the prediction accuracy in certain settings. Additionally, we apply neural posterior estimation for demographic inference for simple and more complex models to highlight its application. For organisms with the sub-population structure, the method can also be utilized to investigate migration events. Finally, we provide a user friendly workflow that enables others to perform neural posterior estimation to their own genetic data.

Phylogenetic probabilistic PCA

Montoya P¹, Morlon H², Joseph J¹, Clavel J¹

¹Université Claude Bernard Lyon 1, LEHNA UMR 5023, CNRS, ENTPE, ²Institut de Biologie École Normale Supérieure, Université PSL, CNRS, INSERM

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

It is common practice in evolutionary biology to study the evolution of phenotypes from multiple traits. Then, principal component analysis (PCA) is probably the most commonly used technique to summarise the information in a few variables, making easier its handling and interpretation. For comparative data, a phylogenetic version of PCA is needed to take into account the relationship between species and to avoid spurious conclusions. However, to apply phylogenetic PCA, the evolutionary model underlying the data set must be defined, which is usually unknown, and only a Brownian motion process can be used when the number of variables exceeds the number of lineages. This becomes a limitation since the reliability of the conclusions depends on the PCA being performed under the correct evolutionary model. To overcome this limitation, we implemented a probabilistic PCA in a phylogenetic framework. This technique, phylogenetic probabilistic PCA (P3CA), is developed from a continuous latent variable model where it is possible to evaluate a likelihood function for a multivariate normal distribution. This allows to evaluate the fit of multiple evolutionary

models to the data and then, without the need for assumptions. Also, we formulate an Expectation-Maximisation (EM) algorithm, which potentially makes it faster to reach a solution, but also allows to deal with missing cases. Using the implementation for Pagel's lambda model and simulations, we evaluate the accuracy of the P3CA and find a high accuracy when a complete dataset is used in both, when the number of lineages exceeds and is exceeded by the number of variables. If missing cases are included (up to 10%), the evolutionary parameter describing the model is slightly underestimated. This underestimation still allows to recover the information in the new reduced space, measured by the similarity between the loadings. To illustrate, we applied the P3CA to geometric morphometric datasets describing the skull shape of crocodylians and bats. We expect that having the formulation for phylogenetic PCA based on a probabilistic, to address some of the limitations for using this primary dimension reduction technique in the study of phenotypic evolution, helping to deal with and understand the large volumes of high-density data currently being generated

The evolution of reversible plasticity in stable environments

Walasek N¹, Panchanathan K², Frankenhuis W^{1,3}

¹Institute For Biodiversity And Ecosystem Dynamics, University Of Amsterdam, ²University of Missouri,

³Max Planck Institute for the Study of Crime, Security and Law

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

Reversible plasticity, i.e. the ability to deconstruct phenotypic specializations based on environmental conditions is widespread in nature. Despite its ubiquity, few mathematical models have explored the evolutionary selection pressures that favor trait reversibility. Here, we present a model of the evolution of reversible plasticity in which organisms incrementally tailor phenotypes to their environment based on cues. Contrasting previous work the environmental state varies between but not within generations. We highlight two results. First, although plasticity in construction is

typically highest early in ontogeny, we observe the highest levels of plasticity in deconstruction in mid-ontogeny. Second, we find that reversibility often evolves in ontogenetically stable environments. Thus, contrasting common beliefs, our model shows that reversibility does not require environmental change during development—as long as organisms are initially uncertain about environmental conditions. Our model provides new insights into the capacity for reversibility in species that have evolved in ontogenetically stable environments.

The value of ‘simple’ models in the era of complexity: Case studies from sexual selection

Lehtonen J¹

¹University of Jyväskylä

MEETING ROOM 129+130, August 19, 2025, 11:00 AM - 1:00 PM

Access to technological advances and ever more complex models provides opportunities we could previously only dream of. However, this does not imply that simpler models and classical modelling methods have become obsolete. I argue for the opposite case: that instead of moving away from simple methods, the increasing prevalence of very complex models should be accompanied by attempts to understand root causes of phenomena using classical and often simple approaches. In the best-case scenario, distilling models into the simplest possible forms can yield insight regarding biology and causality that is inaccessible using very complex models. I

briefly discuss examples from past decades where a very simple model has brought clarity to a range of complex models. I then turn to my recent work on sexual selection, where I have used simple models to bring clarity to debated theoretical issues, or to controversial results arising from large-scale data analysis. While simplicity of a model does not guarantee truth, if two theories are otherwise on an equal footing, the simpler ones, explaining the most using the least are typically preferable. I argue that sometimes we can be blinded from both the right questions and from the right answers if the focus is solely on complex methods

The variance world: the era of location-scale models in evolutionary meta-science

Drobnia S^{1,3}, Nakagawa S^{2,3}, Mizuno A², Yang Y³, Lagisz M³

¹Jagiellonian University, ²University of Alberta, ³University of New South Wales

MEETING ROOM 129+130, August 18, 2025, 10:30 AM - 12:30 PM

Understanding how both the mean and variance of traits differ among species and lineages is fundamental to unveiling macroevolutionary patterns. Yet, traditional phylogenetic comparative methods primarily focus on modelling mean trait values, often overlooking variability and heteroscedasticity that can provide critical insights into evolutionary dynamics. We introduce phylogenetic location-scale models (PLSMs) and location-scale meta-analyses, a novel framework that jointly analyzes the evolution of trait means and variances. This dual approach captures heteroscedasticity and evolutionary changes in trait variability, allowing for the detection of clades with differing variances and revealing patterns of adaptation, diversification, and evolutionary constraints. Extending PLSMs to a multivariate context enables simultaneous analysis of multiple traits and their covariances, facilitating the testing of hypotheses about evolutionary

trade-offs, pleiotropy, and phenotypic integration. By modelling covariances between phylogenetic effects in both the location and scale (variability) parts, we can discern whether changes in one trait's mean or variance are associated with changes in another's, thereby offering deeper insights into the mechanisms driving trait co-evolution, and co-divergence or "contra-divergence". We also describe how an extended version of PLSMs incorporating within-species variability can enhance our understanding of trait convergence and divergence arising from ecological and environmental factors. Our framework provides an innovative and flexible tool for exploring macro-evolutionary patterns by jointly modelling trait means and variances. Importantly, PLSMs can be used to reassess almost all previously published comparative data, providing new evolutionary insights and enriching our understanding of the diversity of life.

Trend-filtered support vector machine to detect natural selection from genomic autocovariation

Amin M¹, DeGiorgio M

¹Florida Atlantic University

MEETING ROOM 129+130, August 18, 2025, 10:30 AM - 12:30 PM

A major challenge in evolutionary genomics is accurately identifying and characterizing natural selection from genomic data. The wide availability of dense whole-genome datasets has enabled researchers to analyze and localize genetic variation within populations. Powerful supervised machine learning methods allow researchers to extract spatial information about genetic variation across the genome and detect traces of natural selection in light of the many genetic, demographic, and ecological influences that might mask adaptive signatures. However, methods such as convolutional neural networks do not preserve spatial information and often suffer from high computational complexity due to their large number of parameters. In contrast, trend filtering directly models the autocovariation of neighboring features, ensuring that spatial relationships remain intact. When integrated into a standard linear model, such as a support vector machine, trend filtering offers a natural framework to create powerful predictive models while retaining the spatial integrity of the input. Here, we introduce SKINET, which employs a

novel trend-filter kernel within a support vector machine framework and applies it to the task of detecting and characterizing regions affected by positive natural selection. This new kernel that we mathematically derived can be readily plugged into a standard SVM classifier or regressor framework, and represents a powerful extension of a linear model that provides prediction performance of natural selection comparable to contemporary deep learning-based methods. Specifically, SKINET not only distinguishes regions under positive natural selection from neutrally evolving regions but also functions in a regression framework to estimate associated adaptive parameters. Moreover, applying SKINET to empirical human genome variation identifies adaptive candidate genes consistent with previous findings while also uncovering novel adaptation targets (e.g., FAM177A1) linked to cancer. Though illustrated on human genomic data, SKINET flexibly handles summary statistic and unphased multilocus genotypes as input, making it suitable for application to non-model organisms.

S04 - Ageing outside of the box: insights from unusual and non-model species

A life history model of continuous growth and negligible senescence under resource allocation trade-offs

Soukainen A¹, Avila P

¹University Of Helsinki

POSTER SESSION 2 - **P02.012**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The evolution of aging remains as one of the unanswered questions in evolutionary biology. Long-lived organisms tend to be characterized by prolonged growth periods or even indeterminate growth, in which growth continues throughout their lifespan. We present a mathematical model with resource allocation schedules as evolving traits that explores the connection between indeterminate growth and negligible and negative senescence. By synthesizing and developing previous theoretical work, we show that the indeterminate growth does not lead to negative senescence as was previously thought. Instead, under different ecological and physiological conditions, optimal somatic maintenance allocation can

lead to diverse age-trajectories of mortality that include slow senescence and sustained allocation to growth. Our work shows the connection between growth strategies, mortality and fertility rates, and details optimal allocation strategies that can lead to even more complex nonmonotonic mortality patterns. While we do not focus on human specific life histories (such as intergenerational transfers), this work also provides clues for the type of ecological and physiological conditions that promote longevity. These findings clarify the role of growth schedules and other ecological and physiological conditions that favour the evolution of ultimately longer lifespans.

A phylogenetic analysis of sporocarp longevity and alternate life history strategies in Polypore mushrooms

Venkatraman G¹, James T¹

¹University of Michigan

POSTER SESSION 2 - **P02.011**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Senescence in mushroom-forming fungi (Agaricomycetes) has received limited attention despite many macrofungi having the potential for infinite hyphal growth as evidenced by the 1500 year old Humongous Fungus (*Armillaria gallica*) and the fairy ring mushroom, *Marasmius oreades*. Fruiting bodies produced by these long-lived fungal species and most Agaricomycetes in general, however, are temporary structures with marked senescence and mortality. The mushroom is often the only part of the fungus that shows degeneration, surviving and remaining functional from a few days to a couple of weeks on average. While certain species invest in numerous small fruiting bodies in clusters, others produce single to a few fruiting bodies ranging in body size from a few millimeters to a meter. Irrespective of which of the aforementioned strategies they follow, most macrofungi invest in ephemeral fruiting bodies, producing new ones each growth season. Interestingly though, certain species within Polyporaceae and

Hymenochaetaceae (commonly referred to as polypores), have diverged from this trend and instead invest in a single or a few limited perennial fruiting bodies and maintain these fruiting bodies over several growing seasons. Every growing season, these fungi produce a fresh hymenium or fertile, spore-producing layer on top of the pre-existing hymenophore. In other words, they invest and maintain a single or a small, limited number of fruiting bodies throughout their life. This marked difference in life-history strategy seems to have evolved only among polypores, many of which also produce hard fruiting bodies with structural tissue differentiation. Given the occurrence of long-lived sporocarps in some polypore species, here, I present results from ancestral state reconstructions of polypores to identify gains and losses of this alternate life history strategy, determine if it has a phylogenetic signal and its potential link to the anatomy of the sporocarp.

Age-related changes and selective disappearance shape variation in bold-shy continuum in guppies

Herdegen Radwan M¹, Raubic J¹

¹Adam Mickiewicz University

POSTER SESSION 2 - P02.009, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The persistence of animal personalities within populations contradicts the optimality principle, assuming a single optimal trait value for all individuals. With the advance of research on the maintenance of animal personalities, two types of data have emerged as particularly needed: (1) longitudinal data, allowing to distinguish population-level and cohort-level variance in personalities, and (2) estimates of additive genetic variance in personality and their genetic correlations with life history traits. While longitudinal studies are beginning to emerge, most research to date has relied on personality measures at a single life-stage, limiting our understanding of the interplay between ages and genotypes. To address this gap, we employed a three-generations pedigree design in a captive guppy (*Poecilia reticulata*) population, measuring boldness at different stages of ontogeny and collecting

long-term survival data. This design enabled us to investigate the genetic contribution to variance in both boldness and survival and examine how this contribution changes across the lifespan in the personality trait. Our results show that boldness decreased with age in genotype-dependent manner. Additionally, boldness was negatively associated with survival. However, while additive genetic effects contributed to variation in boldness, they did not contribute to survival, indicating no genetic basis for the boldness-survival correlation. Lastly, males exhibited higher, more consistent boldness than females. At young ages, the variance in male boldness was primarily driven by additive genetic effects, while maternal effects were more prominent in females. Overall, our findings highlight the complex, dynamic interplay of age, genotype, and sex in shaping individual behaviour.

An Evolutionary Origin of Ageing: Jensen's Inequality and Asymmetric Division in Unicellular Life

Singleton W¹, Kuijper B¹, Buckling A¹, Stefano Pagliara S², Young A¹

¹University Of Exeter, ²University Of Exeter

POSTER SESSION 2 - **P02.016**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Ageing appears intrinsic to unicellular life: subtle within a single cell, yet with complex and variable form across lineages and environments. In model microbial species, such as *E. coli* and *S. pombe*, there is a subtle 'asymmetry' in division where daughter cells consistently differ in growth and survival rates due to unequal inheritance of cellular components. With binary fission, damage accumulates at cell poles and is unevenly inherited by 'old-pole' daughters relative to 'new-pole' daughters. Repeated asymmetric division produces a fractal-like age distribution, with notable plateauing declines along the old-pole lineage. Despite empirical progress, it remains unclear why multiple forms of asymmetry are inherent to cell division, each with distinct structure and variation.

Here, we provide a theoretical synthesis of adaptive evolution of microbial ageing and model transgenerational selection pressures involving multiple inherited components. By extending prior theoretical frameworks (Ackermann et al., 2007; Chao, 2010), we first propose Jensen's inequality as the fundamental criterion for adaptive asymmetric reproduction, applicable to both damage and beneficial components.

1. Jensen's inequality: For a set of values, the average of a convex function applied to each value is greater than the same function applied to the average of the values.

2. Asymmetry definition: Daughter cells inherit opposing deviations in cellular components, creating variance in lineage-specific fitness centred relative to symmetric division.

3. Adaptive Criterion: Asymmetry is selected only when the convex fitness advantage gained by one daughter outweighs the convex fitness loss suffered by its sister, balanced against partitioning costs.

4. Conclusion: Adaptive evolution of microbial ageing inherently depends on convex inheritance-fitness relationships.

We examine how curvature in individual performance functions transforms into lineage-specific fitness, demonstrating how convexity emerges naturally under ecologically plausible selective conditions. This allows asymmetry to evolve even when individual-level

performance functions are linear or concave. For example, cellular survival probabilities with a negative linear relationship to damage transform into a convex lineage-level fitness relationship, due to multiplicative fitness effects across generations. Advances in microfluidics and molecular tagging now enable lineage phenotyping of cell performance and inheritance, allowing for inference of curvature in performance-inheritance functions.

For more complex selective conditions, we analyse the Hessian matrix of lineage-specific fitness and inheritance functions, linking local curvature to fitness outcomes via eigenfunctions of lineage projection kernels. Using an analytical reduction to isolate transgenerational effects, we quantify the local reproductive value of asymmetric division and demonstrate adaptivity across global age distribution bounds.

Interactions: A single heritable component can have multiple interactive effects on fitness landscape curvature, such as damage correlated with division and survival rate. Multiple heritable components can also interact, selecting for 'associativity' in asymmetry, where components become coupled or decoupled in their inheritance.

1. Selection events: Bottlenecks selectively remove low-performance cells, amplifying small trait differences and inducing convexity in fitness through time.

2. Variability in accumulation rates: Non-constant accumulation per generation produces multiplicative, transgenerational lineage effects that favour asymmetric division.

3. Homeostasis: Population growth depends on a concave averaging of division times, with selection to reduce division-time noise. This favours asymmetry in homeostatic control, with tighter regulation in higher-performance cells.

Together, convexity emerges naturally over multiple generations, transforming individual-level performance into lineage-specific fitness, with interactions driving directional associations among asymmetric components. Structured damage asymmetry therefore provides a foundation for phenotypic differentiation across diverse forms of inheritance.

Asymmetric life history trade-offs shape sex-biased longevity patterns

Rees Baylis E¹, Li Richter X^{1,2}, De Vries C³

¹University of Bern, ²University of Konstanz, ³University of Leiden

POSTER SESSION 2 - **P02.015**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Patterns of sex biases in mortality and lifespan vary widely across the animal kingdom, yet there is limited consensus on their underlying mechanisms. A major hypothesis is that sex differences in lifespan are adaptive and driven by sex-specific survival-reproduction trade-offs. Due to differences in reproductive roles between the sexes, natural selection may favour different optima in life history strategies for each sex. In many species, females experience higher mortality costs from offspring production, whilst males can encounter trade-offs linked to mate competition. However, these verbal arguments are based primarily on empirical meta-analyses, lacking formal theoretical predictions. To address this, we developed the first theoretical model to investigate how sex-specific trade-offs shape lifespan evolution in a monogamous mating system. In our model, individuals evolve to optimise a trade-off between reproduction and survival, which operates through access to mating

opportunities in males and offspring production in females. By systematically varying the strength of these trade-offs, we find that either sex can evolve greater longevity, but males outlive females under a broader range of conditions, aligning with evidence from monogamous species. This challenges the common verbal argument that the sex competing for mates (often males) is likely to live shorter due to the survival costs of sexual selection. In our model, female longevity is more constrained than male longevity because the female trade-off between offspring production and survival directly affects the fertility of both sexes. In contrast, the male trade-off involving mate competition has only a weak, indirect effect on female fertility via mating dynamics. As a result, males outlive females under a broader range of conditions. These findings offer new theoretical insights into the adaptive bases of sex-biased longevity and highlight the importance of life history trade-offs in shaping lifespan evolution.

Connecting moth flight timing, ageing and predation risk – a citizen science approach

Zandveld J¹

¹Utrecht University, dep. of biology

POSTER SESSION 2 - P02.014, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

One of the objectives in life-history research is to understand how evolution has shaped current diversity in ageing rates. The historical ecological context plays an important role in explaining life-history diversity between and within species, often showing a relation between food abundance, predation risk and ageing.

Although the evolutionary connection between mortality risk and life-history evolution is well studied in the laboratory, studies in more ecological settings also have shown their significance in evolution and ecology shapes life-histories, but are still scarce.

Many bat- and nocturnal moth species are involved in an arms race, and in response to this predation risk moths often adapted different counter strategies resulting in a diversification of many traits, such as wing shape and wing patterning. However, also life-history diversity can be connected to predation risk within Lepidoptera but is poorly investigated.

Bats have been regarded as the most important predator for nocturnal moths. And the most abundant (Dutch) bat species seem to concentrate their flight activity around specific periods of the night, this may be a suitable system to study temporal patterns of predation and co-evolved life-histories. Although other (a)biotic factors could strongly co-vary with moth life-history, such

as temperature and food abundance, we also expect differential life-history adaptations to be evolved for different moth species that fly at different periods during the night.

Indeed, our first pilot studies seem to show time-dependent flight patterns of different moth species, and an inverse relationship between a species' body size, time-dependent flight and bat abundance. However, as this is early seasonal data, and therefore strongly biased on moth species more abundant in spring.

In this citizen science project we further investigate this relationship over multiple seasons. By using a light trap system that per night samples nocturnal moths only on specific time slots, the next morning visitors of a botanical garden can contribute to this project by determining the caught individuals. When performed multiple nights, locations, and time intervals, this citizen science data may contribute on determining species-specific flight patterns.

Additional measurements on ageing-related life-history characteristics, their phylogenetic distribution, and their relation to bat predation risk could show whether (certain taxa) of nocturnal moths can serve as potential new model system to study the ecological piece of the puzzle explaining diversity of ageing.

Environmental influences on sex-specific senescence in Soay sheep: insights from a longitudinal study

Drake E¹, Ravindran S¹, Bal X¹, Pilkington J¹, Pemberton J¹, Nussey D¹, Froy H¹

¹University Of Edinburgh

POSTER SESSION 2 - **P02.010**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sex is a major source of variation in senescence rates and sex differences in senescence can be seen in a range of taxa and across a range of traits. The energetic costs of reproduction are expected to be unequal between the sexes, with males, particularly those from polygynous populations, allocating more energy towards secondary sexual characteristics and sexual behaviour and resulting in higher mortality costs to males. However, a recent meta-analysis of over 100 wild mammals did not find any evidence of consistent sex-differences in ageing rates. In this work, we aimed to test whether sex-differences in the expression of senescence rates are dependent on environmental conditions. Although age-related susceptibility to extrinsic hazards is well-documented in humans, examples from natural populations are still rare. Despite predictions on how both sex and environmental hazards influence ageing rates, theory and empirical study of the combined consequences of these two factors on senescence are both limited and of mixed results. Using the long-running individual-based study on the Soay sheep of St Kilda, Scotland, we utilised almost 40 years of data to investigate the differences in survival and reproductive senescence between the sexes, and if these differences were dependent on population size. The Soay sheep are a sexually dimorphic, polygynous population of free-living sheep, known to face wide variation in environmental conditions. High population sizes, associated with increased competition for resources and increased parasite burdens, are known to influence over winter survival and male reproductive success. We predicted that the interaction between the costs of sexual selection and increased susceptibility to environmental conditions with age would lead

any differences in senescence rates between the sexes to be exacerbated under high population sizes. We tested the interactions between age, sex, population size, and their associations with annual survival, annual breeding probability, offspring birth weight and recruitment success of females, and annual offspring number of males. Although we found both sexes experienced decreasing survival probability with age, there was no difference between the sexes in the rate of survival senescence. Across the age range, high population sizes decreased survival probability, although there was no effect of population size on the rate of survival senescence or the lack of difference in survival senescence between the sexes. We also present here the first evidence of senescence in male reproductive success for this system. Both sexes showed significant rates of decline in annual breeding probability with age, although there was no difference between these slopes. Neither the senescent slope of males or females were influenced by population size, nor was there any association between population size and breeding probability. Although female recruitment success and offspring birth weight were both found to senesce, the rate of decline of neither trait were impacted by population size, although offspring birth weight was generally reduced under higher population sizes. Male annual offspring number was also reduced at higher population sizes, and the senescent rate of this trait was significantly faster at high population sizes. This work aims to fill a gap in ageing research, by investigating the causes of variation in senescence rates, and how the interactions between condition and the environment can influence the expression of senescence.

Epigenetic Clocks of Soay Sheep

Barnard L¹

¹University Of Sheffield

POSTER SESSION 2 - P02.008, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Ecologists studying wild animals are often interested in understanding the how and why individuals age, and whether ageing rates vary by individual. Recent technical advances in predicting ageing in humans and mice are now being applied to wild animals. First generation epigenetic clocks are used to estimate chronological age of an individual based on its methylome. The methylome is made up of CpG sites, some of which gain or lose a methyl group, through (de)methylation, at a constant rate through lifespan. The difference between this epigenetic age and actual chronological age can be used to estimate individual ageing rates. Second generation clocks, such as the human PhenoAge and GrimAge clocks incorporate phenotypic health and disease risk factors such as smoking pack years. These clocks can be used to assess directly predict biological age and potentially the time to death. Following this I am asking the question, can these first and second generation epigenetic clocks be built for a wild animal context, to measure chronological age, biological age, and to

predict time to death? The long-term data of the Soay Sheep of St Kilda provides the perfect study system to answer this question. Individuals have been sampled repeatedly throughout their lifetime, providing a wealth of longitudinal life history data, including phenotypes that show patterns of senescence. Based on the methylomes of around 1000 samples, I built a clock using elastic net regression, which selected the CpG sites that best predicted age. Having created a chronological clock, the next step is to build in markers of biological age. Identifying which phenotypes can together predict animal age and health will help pinpoint CpG markers of biological ageing. Phenotypic measures such as immunological assays, number of adult teeth, and parasite burdens may indicate both age/maturity and condition of an individual. Combining these with epigenetic markers could produce powerful clocks for both chronological and biological age to deepen our understanding of diverse trajectories of life in the wild.

Exploring the causes of lifespan differences among dog breeds: a burgeoning model for longevity research

Gonzalez Voyer A¹, Bargas Galarraga I¹, von Hardenberg A²

¹Universidad Nacional Autónoma De México, ²University of Pavia

POSTER SESSION 2 - P02.007, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Animals show substantial variation in lifespan, often associated with body size. Across species, larger animals tend to live longer than smaller ones. However, within species, larger individuals typically have shorter lifespans, both in wild and in domestic animals. This apparent contrast highlights the need to understand the factors driving lifespan variation across and within species. The domestic dog is a burgeoning model for longevity research: most extrinsic causes of mortality are controlled and breeds show extreme phenotypic variation, with a twenty-fold range in body size, and a two-fold difference in lifespan among breeds. Because extrinsic mortality is largely absent in dogs, a promising approach to understanding among-breed differences in lifespan is exploring whether there are breed-specific susceptibilities to different diseases. Previous work, for example, suggests that larger breeds are more susceptible to certain types of cancer. The evolutionary history of dogs also provides a valuable opportunity to analyze the influence of shared ancestry and the hybridization events that have given rise to modern breeds on disease susceptibility. First, we assessed whether variance in mortality due to different

diseases could be attributed to shared ancestry and hybridization events. Second, we analyzed the association between weight, growth, reproductive investment, and breed susceptibility to die from specific diseases, accounting for phylogenetic non-independence. We used published data from the Veterinary Medical Database (VMDB) combined with breed-specific data on adult size and life history. We found that the variance explained by shared ancestry and gene flow differed across disease types. Larger breeds were more likely to die from neoplasia, infectious diseases, and gastrointestinal, hematopoietic and musculoskeletal diseases. In contrast, smaller breeds were more prone to degenerative and urogenital causes of death. Greater reproductive investment was associated with reduced mortality from congenital, degenerative and inflammatory causes, independent of body size. These results highlight the role of the evolutionary history and the interplay between life history traits – specifically body size and reproductive investment, in shaping disease susceptibility and lifespan variation across domestic dog breeds.

Extreme Sexual Size Dimorphism: Sex-Specific Growth Pattern in a Spider

Prezelj T^{1,2,4}, Kralj-Fišer S^{1,3,4}, Debes P⁵

²University of Ljubljana, Faculty of Education, ³University of Primorska, Faculty of Mathematics, Natural Sciences and Information Technologies, ⁴Postgraduate School of the Research Centre Of The Slovenian Academy Of Sciences And Arts, ⁵Hólar University College, Department of Aquaculture and Fish Biology

POSTER SESSION 2 - **P02.020**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Female-biased sexual size dimorphism (SSD), where females grow significantly larger than males, is common in invertebrate species. While SSD has been widely studied from evolutionary and ecological perspectives, its proximate mechanisms remain poorly studied. However, understanding the developmental pathways in each sex, including differential growth patterns that give rise to SSD, is crucial to uncover the mechanistic basis of SSD.

Few species exhibit SSD as extremely as the African hermit spider, *Nephilengis cruentata*. Females are on average 75 times heavier and develop 2.3 times longer than males, which suggests that females may grow both, longer and at faster rate than males. Previous research indicates that variation in adult body mass is affected by hatching season. Adult body mass is primarily influenced by direct genetic effects in females and maternal effects in males. Although body mass is often used as a proxy for body size, it is more susceptible to short-term environmental influences than carapace width (CW), which grows in a determinate and discrete manner. As such, CW may provide a more developmentally stable and informative measure of body size.

In this study, we investigated the growth pattern—defined as the growth rate over developmental time—in *N. cruentata*, using CW as a proxy for body size. To compare growth patterns between sexes, we monitored 400 females and 1,203 males, measuring individual CW at least twice during development, from hatching to maturation. In addition to examining sex-specific growth trajectories, we also tested whether these patterns varied with hatching season.

In both sexes, CW increased with age in a non-linear fashion, but the growth pattern differed substantially between sexes. Both sexes initially exhibited a linear growth rate and did not differ in CW until approximately day 60, when males, upon reaching the subadult stage, began to slow their growth. In contrast, females continued growing at a similar rate until around day 200—when they reached the subadult stage—after which their growth also slowed. This implies that females grow bigger due to prolonged period of fast growth, not due to generally faster growth rate over development. At the average developmental age, females had CW of 1.198 mm (95% CI = [1.095, 1.311]) wider than males, and was significantly influenced by hatching season. However, while body mass at maturation was correlated with hatching season, adult CW was not, reinforcing its value as a more stable indicator of adult body size. Ultimately, adult females developed carapaces that were, on average, 3.76 times (95% CI = [3.23, 5.52]) wider than those of adult males.

Taken together, our findings offer novel insights into the developmental basis of extreme SSD in spiders. The detected sex-specific growth trajectories provide a foundation for future, more targeted investigations into the underlying molecular mechanisms—such as sex differences in gene expression and associated physiological changes—that likely emerge around the period when growth patterns begin to diverge between sexes. This offers a mechanistic link to the emergence of sexual size dimorphism. We also highlight the utility of carapace width as a robust trait for studying growth related to SSD in spiders.

Investigating the Plastic and Evolutionary Effects of Isocaloric Macronutrient Composition on Aging and Organismal Performance in Outbred *Drosophila melanogaster* Populations

Kumar D¹, Mohankumar C¹, S C¹, Kumar N¹, Sura C¹, Tung S¹

¹Ashoka University

POSTER SESSION 2 - **P02.013**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Abstract: Aging is influenced by genetic, environmental, and metabolic factors, leading to diminished physiological functions and heightened disease risk. Nutrition, particularly the balance of proteins and carbohydrates, plays a significant role in this process. However, many studies have been conducted under ideal conditions, not reflecting the environmental stressors present in natural settings. This underscores the need to reassess nutritional interventions within varied environmental contexts. Additionally, some research conflates calorie intake with food composition, limiting applicability. While calorie restriction has shown benefits, it may lead to malnutrition and is impractical for many. Thus, adjusting food quality and macronutrient composition is a more feasible approach. Furthermore, nutritional needs also vary across different life stages, suggesting that stage-specific diets could optimize performance under various stress conditions. Exploring how these tailored diets influence organismal performance and their correlation with longevity remains a crucial area of research.

Materials and methods

I'm investigating the plasticity and long-term evolutionary effects of isocaloric dietary manipulation in outbred *Drosophila melanogaster* populations, varying protein-to-carbohydrate ratios at both larval and adult stages. To assess age-related organismal performance, experiments are conducted at early, mid, and late life stages. I've measured starvation, desiccation, thermal, cold, and osmotic tolerance to evaluate fitness under diverse environmental conditions. To explore the biochemical basis, I've quantified key nutritional reserves like triacylglycerides (TAG) and protein, and used the negative-geotaxis assay as a behavioral proxy for neuromuscular aging.

Results: Single-generation response

A high-protein larval and high-carbohydrate adult diet enhances early-age starvation resistance, while a high-carbohydrate adult diet improves it at mid and late ages. High-carbohydrate diets also boost desiccation resistance across most age points. Thermal tolerance is supported by both high-carb. larval and high-protein adult diets in early life, and by high-protein diets at mid-life. Osmotic stress resistance increases with a high-carb larval and high-protein adult diet. Biochemically, greater TAG and protein levels correlate with improved starvation resistance. Interestingly, flies raised on carbohydrate-rich diets during both larval and adult stages show better performance in the negative geotaxis assay.

Evolutionary response: Flies evolved under high carbohydrate food show better Starvation resistance in females, with no difference in males.

Our results underscore the effectiveness of stage-specific diets in enhancing performance across different stress contexts, offering insights into realistic dietary interventions that promote healthy aging and stress resilience.

Conclusions: We find the impact of both larval and adult nutrition on differential stress response for most of the assays. We also see an interaction between larval and adult nutrition, highlighting the importance of stage specificity and the complexity of nutritional requirements. Finally, the responses in some cases are different between males and females, thus emphasizing the sexually dimorphic nature of diet and its impact on aging and organismal performance. Interestingly, no particular diet improves all stress resilience, and the impact of diet is also age-dependent. Some stress responses correlate positively with longevity while others do not, thus highlighting the complex relationship between longevity and stress resilience.

Molecular and structural diversity of multi-ciliated cell types during larval development in the marine annelid *Platynereis dumerilii*

Mutiara S¹, Jekely G², Arendt D³, Schneider S¹

¹Academia Sinica, ²Living Systems Institute, University of Exeter, ³Developmental Biology Unit, European Molecular Biology Laboratory

POSTER SESSION 2 - P02.003, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Multi-ciliated cells (MCCs) are specialized cells equipped with numerous motile cilia, essential for fluid propulsion and locomotion across a wide spectrum of organisms including vertebrates and invertebrates. Despite their importance, MCCs in marine invertebrates are still relatively understudied. The spiralian marine annelid *Platynereis dumerilii* serves a valuable model for studying ciliated structures during development, exhibiting distinct ciliary patterns and bands in its larval stages. This study aims to provide an in-depth analysis of MCCs in *P. dumerilii* larvae, focusing on their developmental stages, structural organization, and underlying gene expression dynamics.

Materials and methods: To do so we used immunostainings and whole mount in situ hybridization techniques, complemented by two ultrastructural whole-body cellular atlases for a three-day old free-swimming larva and six-day old settled juvenile worm, respectively. To investigate molecular diversity, single-nuclei RNA sequencing (snRNA-seq) was conducted across developmental stages (9, 12, 15, and 48 hpf).

Results: We manually traced 80 unique MCCs, classified into seven distinct subtypes by analyzing over 18,107 basal bodies and 14,069 cilia in one three-day-old *Platynereis* larva. These MCCs exhibited two major organizational patterns: (1) dispersed arrays of cilia in the prototroch, crescent cells, nuchal organs, and telotroch, and (2) aligned arrays of cilia as well as an antero-posterior polarity of basal bodies with and without cilia in para-, meta-, and akrotrachs. Transcriptional profiling through snRNA-seq revealed that early developmental stages (9 - 15 hpf) showed minimal differences in MCC gene expression profiles. However, by 48 hpf, distinct transcriptional signatures had emerged, indicating the establishment of transcriptionally specialized MCC populations. This study provides the first complete mapping and quantification of cilia in a marine invertebrate.

Conclusions: These findings offer valuable insights into the molecular differences between MCCs in ciliary bands of marine invertebrates, serving as an entry point for a molecular dissection of the cell biology of dispersed versus aligned MCCs and contribute to a deeper understanding of cell type changes over evolutionary time scales.

Nonhuman primate species share Alzheimer-like neuropathology with humans

Rigby Dames B^{1,2}, Sansum S^{1,3}, Charvet C², de Sousa A^{1,2,4}

¹University Of Bath, ²College of Veterinary Medicine, Auburn University, ³ Social, Genetic & Developmental Psychiatry Centre, King's College, ⁴Allen Institute for Brain Sciences

POSTER SESSION 2 - P02.018, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The hallmark neuropathologies of Alzheimer's disease (AD) include mature plaques (dense core and neuritic A β plaques), neurofibrillary tangles (NFTs) composed of hyperphosphorylated tau, and cerebral amyloid angiopathy (CAA). Although AD-like neuropathology has been reported in several mammalian species, including domestic dogs and chimpanzees, a comprehensive, phylogenetically contextualised review of these pathologies across nonhuman primates, and broader mammals, remains lacking. This is especially important to investigate in nonhuman primates as they are our closest living relatives.

Following PRISMA (2020) guidelines, we conducted a systematic PubMed literature review targeting reports of A β and tau pathology in 295 nonhuman primate species. Observational and control animal data from peer-reviewed studies were included, while review articles, studies of structural brain changes without pathology assessment, and transgenic or experimentally-induced models were excluded. We collected the data on the presence, distribution, and age of onset of A β and tau pathology types. We aimed to characterise species-specific variation in the occurrence and distribution of AD-like neuropathologies, including

mature plaques, CAA, and NFTs, across nonhuman primates. In doing so, we inferred ancestral states and assessed the presence of phylogenetic signals underlying susceptibility to these pathologies.

To provide a broader phylogenetic context for primate evolution, we expanded our dataset to include 22 diverse non-primate mammalian species alongside primates. In our preliminary analyses, ancestral state reconstructions were performed separately for each pathology type. Across the species sample, the occurrence of CAA, mature plaques and NFTs exhibited a significant phylogenetic signal, suggesting heritable vulnerability among closely related species.

These findings suggest that the development of AD-like neuropathology not only in primates but across mammals is not random, potentially reflecting shared evolutionary or genetic mechanisms underlying AD-like pathology. Furthermore, this dataset enables investigation into patterns of co-occurrence and divergence of Alzheimer-like pathologies, highlighting how plaques, tangles, and vascular pathology are associated and distributed across primate species.

Nutritional trade-offs in model and non-model insects and its consequences for lifespan, reproduction and sexual conflict

Morimoto J^{1,2}

¹University Of Aberdeen, ²Universidade Federal do Paraná

POSTER SESSION 2 - P02.004, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The evolutionary puzzle of aging is often approached through the lens of a few model organisms, yet emerging evidence reveals diverse senescence patterns across the tree of life. Here, I will present two important insights about the interplay between nutrition, lifespan, and fitness. First, I used *Drosophila melanogaster* as a platform for mapping multidimensional nutritional trade-offs across traits, life stages, and sexes. Combining insights from the Geometric Framework of Nutrition, I demonstrate how nutrient balance—not just quantity—can shape nutritional trade-offs between lifespan and all other reproductive and developmental traits. Specifically, my results uncovered clear evidence of nutritional trade-offs, where protein-to-carbohydrate (P:C) ratios simultaneously maximise lifespan also minimise reproduction.

Second, I developed a semi-automated algorithm which allowed me to broaden the perspective across nine insect species using a novel method for reconstructing optimal

nutrient landscapes from published data. The analysis uncovered a moderate but statistically significant phylogenetic signal in lifespan-maximizing diets, implying evolutionary conservation in nutrient-longevity relationships despite ecological and taxonomic diversity. Crucially, sex-specific dietary optima also varied phylogenetically, hinting at deep evolutionary roots of sexual conflict over optimum nutrition. The consequences of such intragenomic conflict remains to be properly investigated, and I provide some urgent questions that need to be uncovered by theoretical and empirical work.

Together, these findings across model and non-model organisms reposition nutrition as a central, but underexplored, determinant of lifespan and aging. This work contributes to a broader, comparative framework for nutritional research related to lifespan which is grounded in relevant ecological and evolutionary contexts.

Surviving on limited resources: effects of caloric restriction on growth, gene expression and gut microbiota in a species with male pregnancy (*Hippocampus erectus*).

Pappert F¹

¹Kiel University

POSTER SESSION 2 - **P02.001**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Caloric restriction (CR) studies have traditionally focused on species with conventional reproductive roles, emphasizing female's greater investment in costly gametes and parental care. While the divergent impact of CR on males and females is evident across species, the factors driving this variation, i.e., resource allocation to reproductive elements as part of distinct life history strategies, remain unclear. To address this, we investigated the effects of CR on development, gene expression, and intestinal microbiota in the lined seahorse *Hippocampus erectus*, a species with male pregnancy, where fathers invest in offspring through gestation. Juvenile seahorses were subjected to ad libitum (AL) or CR feeding for 5 months. CR stunted male growth and brood pouch development, reflecting the energy demands of this crucial parental care trait. However, condition index declined in CR females but not males, while ovarian

weight remained unchanged. Transcriptome analysis demonstrated organ- and sex-specific responses to CR with distinct lipid and energy-related pathways activated in male and female livers, indicative of survival enhancement strategies. CR had minimal impact on genes associated with spermatogenesis, but downregulated lipid metabolic and inflammatory genes in ovaries, emphasizing the importance of pre-copulatory resource allocation in female gametes. CR strongly shaped gut microbial composition, creating distinct communities from AL seahorses while also driving sex-specific taxonomic differences. Our research indicates that nutrient limitation's impact on males and females is influenced by their allocation of resources to reproduction and parental investment. We underscore the significance of studying species with diverse reproductive strategies, sex roles, and life-history strategies.

The ageing methylome of the King penguin

Nitta Fernandes F¹, Davis L, Figueroa M, Le Bohec C, Meyer B, Cristofari R

¹University Of Helsinki

POSTER SESSION 2 - **P02.017**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Understanding global molecular processes related to senescence is essential to unravel how fitness decays with age at a population level. Still, due to difficulties in obtaining large-scale samples and age-related information for most non-model species, our current knowledge about such aging processes in wildlife are limited. One of the best characterised ageing hallmarks is the methylation of cytosines followed by a guanine nucleotide, also known as CpG methylation. Although ageing methylation patterns are well characterised in mammals, these patterns are not always conserved in other vertebrate clades. As an example, key metabolic pathways, such as thermogenesis, are known to have evolved independently in birds, making the generalisation of ageing processes between clades likely erroneous. We explored the ageing methylome of the king penguin (*Aptenodytes patagonicus*), a long-lived seabird with an average lifespan of 20 years-old in the wild, in order to identify key genomic features and pathways related with the ageing process in the species. For those means, we sequenced 96 whole-blood methylomes from males and females of known age, sampled at different time points during their life. After fitting a generalised linear mixed-effects model to the individual CpG methylation frequencies, by setting age and sex as fixed effects, we detected 125,545 CpGs that were correlated with age in autosomes (age odds P-values < 0.01). The majority of age-correlated CpG methylated loci were located in intronic regions, followed by intergenic regions. Among

intronic CpGs, we observed an enrichment in the first intron, hinting towards an importance of the first intron in the senescence process of the species. First intron methylation is suggested to cause gene expression silencing in different vertebrate species. The top CpG related with age in a first intron was located in gene SH3RF3, which is upregulated in human cancer stem-like cells, and could be related to the silencing of tumour genes in younger individuals. Among our top hits located in other introns and exons, we detected CpGs inside gene ARNT2, a transcription factor related to development and responses to environmental stimuli; gene CDKN2C, related to cell growth; and, curiously, a peak of CpGs showing high variance with age was located in the METRNL gene, which is related to brown fat cell differentiation. METRNL is known for its role in adipose tissue browning and insulin sensitivity in mammals, and could become a key biomarker for birds if we consolidate its role in the ageing processes in our target species, but also other birds. Moreover, further investigation of gene expression patterns coupled with DNA methylation should shed light into the actual effects of methylation at the detected loci. Finally, most CpGs correlated with age were located farther than 2000 bp up- and downstream from a gene (i.e., gene deserts), not overlapping with non-coding elements currently annotated in the king penguin genome. These results demonstrate that exclusively focusing on CpGs inside genes may provide us with only parts of the potential patterns related with senescence.

The Mammal That Rewired Insulin Signaling to Live Long and Prosper on an Extreme High-Sugar Diet

POSTER SESSION 2 - P02.021, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Nectar-feeding bats thrive on a diet composed almost entirely of simple sugars, sustaining blood glucose levels exceeding 750 mg/dL—levels that typically induce metabolic disease in other mammals. Yet, these bats live 10–15 years, similar to related species with balanced diets. To investigate this metabolic resilience, we analyzed postprandial gene expression across seven bat species and performed functional assays in primary muscle cells from three species.

Despite intact insulin production, nectar bat skeletal muscle shows insulin resistance, marked by the absence of AKT phosphorylation and glycogen storage. Instead, their muscle cells exhibit spontaneous contractile activity, suggesting enhanced AMPK activation—a key energy sensor that promotes fat oxidation and ketone production. Supporting this, nectar bats elevate circulating ketone levels even

during hyperglycemia, indicating a reliance on lipid metabolism at rest.

Increased lactate levels further suggest a glycolytic shunt via MAPK signaling, diverting glucose away from the TCA cycle. We propose that maintaining high blood glucose provides a circulating fuel reserve, sparing glucose for the extreme energy demands of hovering flight while prioritizing lipid-based metabolism at rest. Additionally, suppressed AKT signaling may activate FOXO3a, a transcription factor linked to stress resistance and longevity.

Together, these findings reveal that nectar bats have rewired insulin signaling to decouple longevity from the harmful effects of chronic sugar intake. This metabolic strategy prioritizes lipid oxidation, energy sensing, and muscle excitability, offering new insights into ageing and metabolic flexibility in mammals.

The relationship between phylogeny and age alignments in mammals

de Sousa A¹, Todorov O², Charvet C¹

¹Auburn University College Of Veterinary Medicine, ²Tasmanian Institute of Agriculture

POSTER SESSION 2 - **P02.019**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Different species develop and age at distinct rates and along divergent trajectories, posing a major challenge for comparative studies. Translating Time is a framework developed to align developmental stages across species. Our online tool, translatingtime.org, implements a model based on a dataset of neurobiological developmental events across diverse mammalian taxa. More recent work by our team has begun to extend this framework to support age alignment across the entire lifespan. In our multispecies models, time points in different species are averaged to create an event scale that is standardized across species spanning from conception (0) to maximum lifespan (1).

Currently, our database includes over 34,000 data points, representing 1,745 unique time points across 2,263 species. Translating ages across species is essential when comparing biological data types that vary over the life course. For example, transcriptomic profiles shift across stages of development and aging since different early gene expression patterns are critical for early tissue formation, and later, there are changes associated with age-associated gene regulatory decline. Age alignments are necessary to calibrate interspecies comparisons of transcriptomic profiles across tissues and cell types.

A major challenge is the lack of homologous time point data across biodiverse species. Some species have been studied intensively from experimental periods starting from conception, while others are only observed postnatally in the wild, often not until they emerge from a nest or burrow. This inconsistency results in missing data. Our framework addresses this using imputation and predictive modeling. However, we cannot extend alignments reliably beyond the age ranges for which robust, homologous data exist. Yet comparative analyses often require age translations at life stages where the timing of biological processes is insufficiently known to determine equivalency with confidence.

To address this limitation, we tested whether phylogenetic information could inform age alignments. Our preliminary analysis compared “hypothetical age equivalencies” which are models that include, but extend beyond, age alignment time points across 62 species. We found a moderate but statistically significant correlation between phylogenetic distance and divergence in trajectories, as measured by Euclidean distance between fitted polynomial curves. This suggests that more distantly related mammals exhibit more divergent life history trajectories, spanning from early development through aging.

We investigated the presence of phylogenetic signal at two time points: birth and death. Species were placed along an altricial-precocial spectrum by calculating the residual of the age in post-conception days at which birth occurs, to determine deviations from the multi-species model prediction. Thus operationalized, placement along the altricial-precocial spectrum was tested for phylogenetic signal. After an initial analysis showed phylogenetic signal, we tested alternative evolutionary models and found that a multiple-regime Ornstein-Uhlenbeck model, with separate adaptive peaks for altricial and precocial species, best explained the data. This suggests that these altricial and precocial species are evolving toward different, regime-specific optima.

We also calculated a residual of maximum longevity, expressed as a percentage deviation from the expected value predicted by the multi-species model. This could be used to identify species with exceptional lifespans to select as model organisms in aging research. An initial analysis revealed phylogenetic signal suggesting evolutionary conservation of the trait.

Our preliminary results shed light on the potential of phylogenetic comparative methods to inform about the evolution of life histories, support age alignment across species, and guide the selection of appropriate model organisms.

The role of selection pressure in the evolution of asynchrony of aging

Tsui C^{1,2}, Briga M³, Komdeur J¹, Burke T⁴, Richardson D², Dugdale H¹

¹University Of Groningen, ²University of East Anglia, ³University of Turku, ⁴University of Sheffield

POSTER SESSION 2 - P02.002, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Ageing, the age-related changes in a trait, is a highly variable process. Studies have investigated variation in ageing among species and individuals. Different traits within-individuals may age differently, yet little is understood about why they differ. Historic theories predicting that ageing should be synchronous across traits are erroneous. Recent theories predict that the rate and onset of trait ageing should be explained by the selection pressure on the trait. To date, there have been no empirical studies examining the role of trait specific selection behind the evolution of asynchrony of ageing. First, we tested for asynchrony of ageing across 13 traits (including a range of morphological, physiological, behavioural and life history traits), in a closed natural population of Seychelles warblers (*Acrocephalus Seychellensis*). Secondly, we examined whether selection on a trait explained their respective ageing trajectories. We quantified synchrony between traits with similar ageing trajectories by comparing the onset and rate of ageing. Out of the 13 traits, 6 exhibited

ageing: body mass, fat score, provisioning rate, telomere length, survival and annual reproductive success, while buffy coat only showed aging in females. There was no support for synchronous ageing among traits although some traits shared similar aging trajectories. Our study adds to growing evidence that ageing is asynchronous. Our preliminary finding of ageing in traits expected to have stronger selection: e.g. survival and reproductive success, but not in a trait expected to have weaker selection e.g. wing length seems to indicate some weak support for newer theories that traits under stronger selection experience more ageing. We will next quantify selection on traits with significant ageing and test the hypothesis that traits with stronger selection should have more rapid and an earlier onset of ageing. We will present the results and discuss the implications of the study in the presentation. To our knowledge, this study will be the first empirical study to demonstrate the role of selection pressure behind the evolution of asynchrony of aging.

Aging in ants: from the individual to the colony level

Jaimes Nino L^{1,2}, Bieuville M², Ronget V², Kokko H², Foitzik S¹

¹Behavioral Ecology and Social Evolution, iomE, Johannes Gutenberg Universität, ²Theoretical Evolutionary Ecology, iomE, Johannes Gutenberg Universität

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

Some species exhibit indeterminate growth, growing continuously with an increase in fertility long after maturity. For example, ant colony size continues growing after the queen's maturation – beginning of sexual production – and ant queens increase the production of sexuals with age. Two features of the ant *Cardiocondyla obscurior* imply that the strength of selection against senescence is maintained after the queen's maturity. (1) The mortality rate of ant queens is low compared to their average mortality past their fertility peak, with mortality only increasing rapidly very late in life. (2) There is no evidence for the Lansing effect, even if interpreted sensu lato as a negative effect on offspring fitness of advanced maternal age. In our project, we look beyond the individual to understand how colonies are established, mature, and age. New colonies are produced

by budding, where some individuals leave the mother colony on foot to establish a new daughter colony. How the superorganism ages will depend on the maturation time too, i.e., funding of daughter colonies by budding, and the allocation of individuals into new versus old colonies. Analogous to yeast, in which asymmetric budding produces a cell with rejuvenated genetic material and older with the accumulated DNA damage, we aim to know if new colonies were formed by old queens or young queens. Lastly, we experimentally varied the extrinsic mortality experienced by colonies to investigate whether colonies support theoretical predictions regarding colony maturation time. Our study sheds light on the understanding of senescence in organisms in which size affects mortality risk and other demographic determinants of aging.

Divergence in allelic variation and gene expression in molecular networks that underly aging between fast- and slow-aging garter snakes.

⁵University of Minnesota, ⁶Luther College, ⁷University of Wisconsin La Crosse

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

Background. Understanding the genetic underpinnings of natural variation in rates of aging can identify mechanisms for how such variation evolves. The process of organismal aging has been explained by many cellular networks in laboratory model organisms. Much less is known about whether these networks are conserved and causative in wild populations. A thorough understanding of the mechanisms of aging requires examination of patterns in wild populations, since this is where aging evolved. Here we use a long-studied system of garter snakes (*Thamnophis elegans*) in the Eagle Lake basin (Lassen County), California US that has replicate populations characterized by two life history strategies of fast-aging (faster growth to larger body size, more frequent reproduction, and shorter lifespan) and slow-aging ecotypes. Previous research found phenotypic divergence between ecotypes in body size, color pattern, immune function, and age-related cellular signaling pathways. Here we test whether there are genetic underpinnings for these divergent ecotypes by examining variation and expression in gene networks within several major hallmarks of aging: Metabolic Function (including Insulin and Insulin-like Signaling [IIS] and Oxidative Phosphorylation), Macromolecule Damage and Repair, and Stress Adaptation.

Materials and Methods. We assess levels of genetic divergence among populations of the two ecotypes in (1) hepatic transcriptomic responses to acute heat stress using RNAseq, and (2) sequence variation from whole genomic sequencing data and targeted sequence capture data for putative aging loci through genetic distance (FST and DXY), and amino acid polymorphisms between fast- and slow-aging snakes.

Results. Through differential gene expression and pathway enrichment analyses we find significant divergence between the fast- and slow-aging ecotypes in their response to heat stress,

specifically in their regulation of the IIS, Oxidative Phosphorylation, and DNA repair molecular networks. The slow-aging ecotype had individuals with greater coordinated transcriptomic response to heat stress relative to fast-aging, which may result in the coevolutionary process for stress-resistance and senescence-resistance. At the level of sequence variation, we find allelic divergence in key nodes in these networks. At the intersection of divergence in gene expression and divergence in sequence variation, we find many Insulin-Signaling genes (including IGF2, and IGFBP3, IRS4, GSK3B, MAP3K1, and FOXO3), many Heat Shock Proteins, and DNA repair genes (including XRCC3 and RAD54B) that have diverged in gene expression and sequence variation. Many of the genes and pathways identified as divergent among our fast- and slow-living ecotypes have been associated with longevity in several long-lived organisms.

Conclusions. Using natural populations of garter snakes that have diverged in their physiology and life history strategies, we have documented putative mechanisms through divergence in regulation and nucleotide sequence of candidate gene networks underpinning three hallmarks of aging: metabolic processes, macromolecule damage and repair, and stress adaptation. In doing so, we have demonstrated these candidate molecular networks regulating aging translate from lab models to natural populations. In addition, the interaction between ecotypes in response to heat stress indicates many more pathways are diverging than just the ones we highlighted in this study, suggesting natural populations and non-model organisms likely have mechanisms for diversification in aging processes beyond those currently identified in lab models. This research provides insight into our understanding of how life history traits, including aging, evolve, and highlights the importance of studying cellular networks of aging within and across species.

Germline mutation rate and somatic maintenance improved simultaneously by reduced insulin signalling

Duxbury E¹, Godden A¹, de Coriolis J¹, Carlsson H¹, Immler S¹, Maklakov A¹

¹University Of East Anglia

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

Disposable soma theory maintains that organisms age due to trade-offs between an immortal germline and a disposable soma. Yet increasing evidence demonstrates that lifespan extension is not always accompanied by a fecundity cost. One of the most compelling examples of apparent cost-free lifespan extension is the downregulation of adulthood insulin/IGF-1 signalling (IIS) in *C. elegans* nematodes, using *daf-2* RNA interference (RNAi) knockdown in adults, making them extremely long-lived and stress-resistant with normal reproduction. We tested whether this apparent absence of a trade-off between survival and reproduction, can be explained by the hidden costs of reduced germline maintenance, leading to a trade-off between parental longevity and offspring fitness. We ran a multigenerational mutation accumulation (MA) experiment to directly compare germline mutation rates in replicate *daf-2*

RNAi and control MA lines after inducing germline mutations using UV irradiation. We tested whether increased investment into somatic maintenance via reduced IIS resulted in increased mutation rate. Contrary to predictions, we found reducing IIS results in reduced germline mutation rate. Using high coverage whole genome sequencing of the MA lines, we showed reduced rates of germline point mutations and transposable element insertions under reduced IIS in UV-irradiated MA lines, with fewer missense mutations in genes with essential functions in development or reproduction. Interestingly, functional inheritance of RNAi was required for the benefits of multigenerational *daf-2* RNAi. Our results suggest that reduced insulin signalling improves both somatic and germline maintenance. We discuss evolutionary implications of these findings.

Lifespan extension in *Heliconius* butterflies: from ultimate to proximate mechanisms

Foley J¹, **Montgomery S**¹

¹University Of Bristol

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

The diversity of lifespans across the animal kingdom has long been a subject of interest for evolutionary biologists. With maximum longevities ranging from a single day in adult mayflies up to several centuries in the ocean quahog, how have some organisms managed to evolve such long lives? With a globally ageing population, this question is of growing biomedical interest – and the high conservation of mechanisms of ageing has researchers increasingly looking to non-model systems for the answers.

The remarkable lifespans of the *Heliconius* butterfly genus, stretching up to almost a year, rank among the longest recorded in butterflies. Crucially, this lifespan extension has occurred relatively recently in evolutionary time, with recorded lifespans of only 1-2 months for their nearest relatives in the *Heliconiini* tribe. This longevity has been

linked to the evolution of a unique pollen-feeding behaviour in *Heliconius*, which co-occurs with a suite of other behavioural and physiological traits that are absent in the non-pollen-feeding *Heliconiini* outgroups. Here, we combine survival analyses, behavioural assays, and transcriptomic work across the lifespan of *Heliconius hecale* and the shorter-lived *Heliconiini* outgroup *Dryas iulia*, under both pollen-fed and pollen-deprived diets. This approach allows us to construct an exhaustive profile of ageing in these butterflies, shedding light on the evolutionary trajectory of *Heliconius*' lifespan extension and some of the key molecular mechanisms that underpin it. Our results help to disentangle the link between diet and ageing in *Heliconius*, adding a new case study to the canon of noteworthy agers, and providing valuable insights into the evolution of long life.

Peto's Paradox for fungi

Aanen D¹, **Auxier B**¹

¹Wageningen University

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

Peto's paradox refers to the absence of a correlation between body size and cancer risk in animal species. The solution of this paradox comes from the realisation that natural selection interacts with the life history of a species and favours adaptations that suppress cancer through the expected period of fertility of an organism. So tall -and typically long-lived- species must have robust cancer-suppressing mechanisms to achieve a low lifetime cancer risk, while small -and typically short-lived- species can do without, to achieve the same low lifetime-cancer risk. It seems impossible to apply this logic to modular organisms, such as fungi, since they do not have a fixed body plan and thus can continue to increase in size. Moreover, what are cancerous mutations in modular organisms, which do not have an early separation between soma and germline? I propose an analogue of Peto's paradox for fungi, based on the following experiments, observations and logic: i) The mycelial lifespan of fungi varies extensively between species and is -at least partially- determined by extrinsic factors such as fire, finite and discrete growth substrates or

ecological strategy; ii) Using experimental evolution, we demonstrated that short-lived fungi predictably evolve cheating variants during clonal propagation. Those cheating variants are analogous to cancer mutants in animals, since they have a competitive benefit within the fungal mycelium, but reduce mycelium-level fitness; iii) In contrast, naturally long-lived species, such as the fairy-ring fungus and the honey fungus, are resistant to the evolution of cheating variants and so far, experimental evolution has failed to show the selection of cheating variants; iv) Consistent with the resistance of long-lived species against cheating mutants, those species typically have mechanisms that we hypothesised reduce the selective scope of selfish mutants, such as a low mitotic mutation rate, a higher degree of cell compartmentalisation, and clamp connections. Analogous to Peto's paradox, we thus propose a constant and low lifetime cheating risk for fungi, which explains the low natural occurrence of cheating mutants in the kingdom Fungi, which contains species that vary in life expectancy from days to millennia.

Senescence evolution under the catastrophic accumulation of deleterious mutations

Aubier T¹, Galipaud M²

¹CNRS, Université de Toulouse, ²ETH

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

For aging to evolve, selection against mortality must decrease with age. This prevailing view in the evolutionary theory of senescence posits that mutations with deleterious effects happening late in life—when purging selection is weak—may become fixed via genetic drift in the germline, and produce a senescent phenotype. Theory, however, has focused primarily on growing populations and the fate of single deleterious mutations. In a mathematical model, we demonstrate that relaxing both of these simplifying assumptions leads to unrealistic outcomes. In density-regulated populations, previously fixed deleterious mutations should promote the fixation of other deleterious mutations that lead to senescence at ever younger ages, until death necessarily occurs at sexual maturity. This sequential fixation of deleterious mutations is not promoted by a decrease in population size, but is due to a change in the strength of selection. In an individual-based model, we

also show that such evolutionary dynamics should lead to the extinction of most populations. Our models therefore make rather unrealistic predictions, underlining the need for a reappraisal of current theories. In this respect, we have further assumed in our models that the deleterious effects of mutations can only occur at certain ages, marked, for instance, by somatic or physiological changes. Under this condition, we show that the catastrophic accumulation of deleterious mutations in the germline can stop. This new finding emphasizes the importance of investigating somatic factors, as well as other mechanisms underlying the deleterious effects of mutations, to understand senescence evolution. More generally, our model therefore establishes that patterns of senescence in nature depend not only on the decrease in selection strength with age but also on any mechanism that stops the catastrophic accumulation of mutations.

Senescence in an unusual invertebrate model: insights from the tsetse fly

English S¹

¹University Of Bristol

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

Here, I show what insights we can gain on understanding the evolution of senescence by considering a viviparous insect with high maternal investment - the tsetse fly - as an unusual model. While tsetse are unitary and sexually reproducing, they contrast typical systems to study survival and reproductive senescence due to their viviparous reproduction (mothers give birth to single offspring the same size as the parent,

iteroparously across their relatively long life) and role as vector of trypanosome parasites. Here, I show how what we have learned about survival and reproductive senescence using a combination of theory, lab and field studies in tsetse, and the implications of this research both for testing predictions about the evolution of ageing and for understanding its role in in epidemiological models of tsetse-borne disease.

The antagonistic pleiotropy and disposable soma theories of ageing differ in their predictions of age specific survival and fecundity

Van Den Heuvel J¹, Doekes H¹, Zwaan B¹

¹Wageningen University and Research

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

A main question in evolutionary biology in general and ageing research specifically, is how genetic variation translates into phenotypic variation. Furthermore, whether new mutations affect lifespan and other traits solely negatively, via mutation accumulation, or through trade-offs remains largely undetermined. Trade-offs are expected to affect certain traits negatively, while others are altered positively. In the history of evolutionary theories of ageing, two theories have resided next to each other that consider trade-offs as a basic mechanism to describe ageing.

These two classical evolutionary theories of ageing - antagonistic pleiotropy (AP) and disposable soma (DS) theory - are based on trade-offs at different biological levels (genetics and physiology) but many predictions of these theories overlap. However, a key difference between AP and DS lies in when a new mutation negatively affects survival, compared to its positive effects on other traits. AP assumes that negative effects are expressed relatively late in life compared to positive effects on for instance fecundity, while DS assumes that an increase in fecundity directly has negative consequences survival.

We use a life history theory model to test whether this difference in timing of these

effects results in different predictions for life courses, specifically age-dependent survival but also fecundity. We find that AP predicts a threshold age for these traits, such that fecundity and survival for age classes below this threshold are maximized while no individuals survive beyond this threshold age. On the other hand, DS predicts selection of mutations that cause a monotonous increase in mortality, which leads to survival curves that are seen in real life. Furthermore, in simulations that contain only a small proportion of AP, compared to DS mutations, the resulting life course predictions are equal to AP predictions.

We conclude that if in our world trade-offs are based solely or partially AP mutations, survival curves would look very different from the ones found on planet earth. Hence, genetic effects that have previously been attributed to AP are likely of the DS type. This means that (negative) phenotypic effects that are only observed late in life must have a physiological basis early in life. These findings have important implications for how age-dependent mutations affect fitness-related phenotypes, such as fecundity and survival, and should therefore be carefully considered when generating and interpreting empirical data.

The selection shadow measured at the single-cell type level

Somel M¹, Yıldız N, İzgi H, Rahimova F, Altıntaş U, Turan Z

¹Middle East Technical University

MEETING ROOM 129+130, August 19, 2025, 2:00 PM - 5:00 PM

In recent years various studies have shown that genes expressed at old age (old-biased genes) evolve under weaker purifying selection than young-biased genes. However, these results were based on transcriptome profiles of either bulk tissue samples (from primates and rodents) or whole-body samples (of Diptera). It has thus been unclear whether this "selection shadow" signal might be simply caused by tissue and cell type composition changes over life, and also whether it might be observed across a wider range of species. Here we first confirm that the signal of weak purifying selection on old-biased genes can be observed across brain and/or liver bulk tissue transcriptomes from a wide range of

metazoa, from the naked mole rat to chicken to fruit flies. We then show that the signal can also be observed in single cell type transcriptomes from mice. Although different cell type transcriptomes appear to be under diverse levels of overall purifying selection, comparing their profiles in young and old animals, the majority demonstrate the selection shadow effect. This marks that the observed signal is not caused by cell type composition changes. We discuss how genetic drift on regulatory and/or coding sequences could be a widespread contributor to ageing phenotypes and how species with negative senescence would be used to gauge these potential contributions.

Bottlenecked but booming: paradoxically strong inbreeding in highly invasive freshwater mussels

Miettinen A¹, Gottenborg Høyer Hansen J¹, Sejrsild Jensen E¹, Stepien C², Tengstedt A¹, Hansen M¹

¹Aarhus University, Department of Biology, ²National Museum of Natural History, Smithsonian Institution

POSTER SESSION 1 - P01.063, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biological invasions threaten global biodiversity and human well-being, which highlights our pressing need to better comprehend still poorly understood invasion processes. Specifically, invasive populations originating from only few founders are expected to exhibit reduced genetic diversity and increased inbreeding. Theory predicts this should often lead to inbreeding depression and restrict adaptation in the invaders. However, successful invasions do often involve severe bottlenecks and founder events. We address this “genetic paradox of invasions” by analysing whole-genome resequencing data of invasive populations of the zebra mussel (*Dreissena polymorpha*). We provide evidence for extremely strong inbreeding in these highly successful invasive populations. We demonstrate that genomes

of the invasive freshwater mussels harbour extensive runs of homozygosity resulting from severe bottlenecks and subsequent inbreeding during the invasion process. We also quantify deleterious genetic variation (genetic load) across populations from the native and invasive range of the species and find indications of the possible role of purifying selection (purging) in facilitating invasion success in these mussels. This study provides a compelling example of a paradoxically successful invader and offers novel insights into the genomic consequences of inbreeding due to founder events and bottlenecks in invasive species. These findings are broadly relevant across taxa and contribute to a deeper understanding of factors affecting invasion dynamics.

Coexistence and Succession in Disequilibrium: Insights from Nematode Communities on Decaying Beetles

Kalirad A¹, Sommer R¹

¹Max Planck Institute for Biology Tübingen

POSTER SESSION 1 - P01.055, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Understanding the processes that shape ecological communities and determine their dynamics in relation to other such communities arranged in space - i.e., a metacommunity - remains central to ecology. The majority of theoretical treatments of this topic rely on models suited to study ecosystems at equilibrium. In contrast, many ecosystems are transient, most notably those that emerge following environmental disturbance, which paves the way for species succession. Despite their long-appreciated importance, such transient ecosystems remain poorly understood.

Materials and methods: In this contribution, I present a novel approach to study the ecological dynamics on the carcass of the *Gymnogaster* beetle, as a model for transient, decaying ecosystems. Following the natural death of a beetle (environmental disturbance), a new habitat is created in which bacteria and fungi decompose the carcass. This creates resources for nematodes — hitherto passive hitchhikers on the beetle — to exit their dormant state in succession, consume bacterial resources, and beget new dormant larvae that migrate into the environment. This life cycle provides a perfect model to address the factors that shape metacommunity composition

consisting of transient communities formed by succession.

Results: We sacrificed *Gymnogaster* beetles sampled from Réunion Island in the laboratory and followed the emergence of nematodes on the carcass. The nematode species that emerged on these beetles exhibited diverse reproductive modes - hermaphroditism and gonochorism - as well as morphological variation in feeding structures. Some nematodes are obligate bacterial feeders, while others exhibit intraguild predation by preying on competing nematodes. To study the dynamics of coexistence in disequilibrium, we computationally reconstructed decaying beetles using an agent-based model, taking advantage of experimentally-derived life-history parameters for each species, i.e. emergence time, sex ratio and fecundity.

Conclusions: Our integrated analysis shows coexistence in transient ecosystems shaped by succession strategies. This work addresses the shortcomings of classical approaches and highlights the importance of transient interactions in ecosystems characterized by disequilibrium. Thus, our work provides a unique experimental and computational framework to synthesize various approaches to metacommunity and species succession theories.

Contrasting genomic signatures of hybridisation across admixed populations of native and invasive *Mytilus* mussels in Australia

Howitt S¹, Popovic I^{1,2}, Ellis R³, Bierne N⁴, Riginos C^{1,2}

¹School of the Environment, The University of Queensland, ²Australian Institute of Marine Science,

³Biosciences, University of Exeter, ⁴ISEM, University of Montpellier, CNRS, IRD

POSTER SESSION 1 - **P01.062**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Species are facing increasing pressure to rapidly adapt in the face of anthropogenic change. Introduced species are frequently used to study rapid adaptation to novel environments and can impose strong selection pressures on native congeners. Hybridisation between native and invasive species can facilitate rapid genetic change in both species by reshuffling the genome to unlock new adaptive combinations or transfer adaptive variation from one species to the other. Studying the impacts of hybridisation on native and invasive genomes can provide insights into how invasive species reshape native genetic diversity and how these new mosaic genomes may respond to selection and facilitate invasive spread. In Australia, two introduced lineages of the European invader, *Mytilus galloprovincialis* (Atlantic and Mediterranean) hybridise with the native mussel *Mytilus planulatus* forming replicated hybrid zones.

Materials and Methods: Here, we characterise hundreds of mussels using a

SNP genotyping panel to examine patterns of hybridisation along the genome. Contrasting these two hybrid zones, we use local ancestry inference, and scans for diversity and differentiation to test if selection has influenced introgression patterns differently in different genetic backgrounds.

Results: We find that admixture is extensive and parental European genotypes are not found. However, the two independent hybrid zones are characterised by contrasting major parent ancestries and locus specific patterns of genetic variation suggesting diverse outcomes of hybridisation among closely related taxa.

Conclusions: These different outcomes indicate hybridisation is context dependent and selection may be acting differently with different invasive genetic backgrounds. The Australian *Mytilus* system suggests the potential for multiple pathways of successful rapid adaptation following hybridisation of invasive species with native congeners.

Evolution of the genetic load in invasive insects: insights from a genomic cross-species study

Lombaert E¹, Beaumé A, Blin A, Da Rocha M, Gautier M, Lapègue M, Guillemaud T, Perrier C, Pochon M, Porro B, Zallio M, Deleury E

¹INRAE

POSTER SESSION 1 - P01.053, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Biological invasions are a major component of global change. Yet it remains unclear why some introduced populations become invasive while others do not. One intriguing hypothesis is the purging of deleterious mutations during the introduction process. Following the introduction of a small number of individuals into a new area, the interplay between genetic drift, inbreeding and natural selection may lead either to the fixation or to the purging of deleterious alleles, affecting individual fitness. We hypothesize that populations that successfully become invasive are those that have purged part of their genetic load.

Materials and Methods: We investigate the purge hypothesis across a broad taxonomic scale, analyzing ten insect species with well-documented invasion histories. For each species, we sampled between five and ten key native and invasive populations, representative of major steps in their invasion routes. We performed whole-genome pool-sequencing and developed a reproducible analysis pipeline to identify, annotate and categorize hundreds of thousands of SNPs per species. This framework enables a quantitative comparison of genetic load between native

and invasive populations, and between species.

Results: As expected, genetic diversity is generally lower in invasive populations compared to native ones, reflecting historical bottlenecks associated with introductions. However, we observe strong interspecific variation in the severity of bottlenecks and the magnitude of genetic load. Across species, no consistent trend emerges regarding the evolution of genetic load: some invasive populations show patterns compatible with purging, while others appear to have accumulated deleterious alleles. These contrasting patterns highlight the complexity of evolutionary trajectories during invasions.

Conclusions: Our multi-species comparative approach suggests that the dynamics of genetic load during invasions are highly context-dependent. While purging may contribute to invasion success in some species, it does not appear to be a systematic outcome. Ongoing work will refine these findings and explore whether specific subsets of genes are more likely to undergo purging. These results emphasize the need for a more nuanced understanding of how demographic and selective forces interact during biological invasions.

Hybridization at the front wave of expansion increases genomic variability within an invasive species of slug, overcoming genetic drift

de Freitas Lacerda L^{1,2}, Alaei Kakhki N¹, Richling I¹, Reise H³, Hutchinson J³, Pereira R¹

¹State Museum of Natural History Stuttgart, ²University of Hohenheim, ³Senckenberg Museum of Natural History Görlitz

POSTER SESSION 1 - P01.054, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Biological invasions pose significant challenges to biodiversity leading to the extinction of native species and to altering ecosystem function. When invasive species colonize new environments, they experience both strong founder effects and demographic expansions, contributing to genetic drift and thus hindering the efficiency of natural selection. Although invasive species are clearly successful in rapidly adapting to novel environments, the source of genetic variation facilitating invasiveness remains unclear. During invasion, hybridization between closely related native and invasive species often occurs, potentially counteracting genetic drift within invasive species and supplying locally adaptive variants that were already filtered by natural selection, ultimately fuelling the invasion process. This study addresses this hypothesis using the invasion of the invasive slug species *Arion vulgaris* that interacts with local subspecies of *A. ater*, leading them to extinction throughout Europe and highly impacting the local ecosystem because of its high predatory behavior.

Materials and Methods: We utilized a comprehensive sampling of the entire known species range sequenced for the whole genome at low coverage to assess delimitation of invasive species and native subspecies and identify possible hybrids between the taxa. Demographic analyses were used to determine the pattern of expansion for invasive species and the pattern of contraction for native subspecies. High coverage data for reference samples was used in determining the most probable species tree, and to quantify introgression between the invasive and different native subspecies using low coverage data. We estimated changes of genetic variability over time and space resulting from the combined action of genetic drift and introgression between native and invasive species, along the range of invasion.

Results: The genetic structure shows that hybridization is a widespread phenomenon in this

system, happening not only between the invasive and native species as a consequence of the invasion process, but also naturally between native subspecies. Demographic analyses showed that the invasive species is going through a process of demographic expansion while native species present a bottleneck, suggesting that their demographic dynamics are correlated. Aside from the ongoing hybridization, we also identified significant introgression between pure individuals of the invasive *A. vulgaris* and the native *A. a. ruber*. Interestingly, despite the expected drift caused by expansion, the genetic variability within the invasive species increases along the invasion wave, which supports the hypothesis that introgression from native into invasive species effectively prevents the loss of diversity.

Conclusions: Our results on the invasive slug *A. vulgaris* over the range of the native subspecies of *A. ater* offer general insights into the sources of genetic variability in the invasive species that potentially allow rapid adaptation during invasion. The invasion of the foreign species into a new habitat is accompanied by a demographic expansion and an initial loss of genetic diversity and increased genetic drift, as only a small fraction of the original population initiates the spread. However, our findings indicate that hybridization between congeneric native and invasive species during the invasion process may counteract this loss by rapidly increasing genetic diversity at the front wave of the invasion process and providing novel genetic combinations within the invasive taxon. Such introgression transfers locally adaptive alleles and can create a genetic substrate for rapid adaptation. This phenomenon, therefore, may be an important mechanism to explain the rapid adaptation of invasive species to novel environments, even under seemingly unfavorable demographic conditions.

Impact of dispersal and spatial processes on niche expansion during invasions

Miller C¹, Draghi J¹

¹Virginia Tech

POSTER SESSION 1 - **P01.061**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Invasive species can have widespread impacts on the ecosystems they enter. However, the process of invasion can also push invaders to evolve. Invasions are potent eco-evolutionary forces, and the process of expanding can lead to evolution even in the absence of the pressures of entering a new community. One empirically established example of this is increased dispersal speed in expanding populations, such as the invasive cane toads in Australia. In this study, we combine knowledge of dispersal evolution during invasions with emerging theory about evolution of niche expansion towards generalism during expansions. Using individual-based simulations, we allow dispersal distance and generalism to evolve individually and then together in heterogeneous landscapes. We expect dispersal distance to increase during invasions, and generalism to be more likely

to evolve. Individually, we find that both traits evolve during expansions as individuals take advantage of opportunity in the less crowded, more resource dense expansion front. When combined, there is the potential for these traits to be synergistic, with more dispersal leading to greater environmental heterogeneity and selection for generalism. However, in our model we see that these traits can also be antagonistic during invasions, with selection on reaching new areas first being so strong that it decreases co-occurrence of traits in the same individual. This study addresses how invaders can evolve during the process of invasions. Understanding the process of invader evolution can alter measures and understanding of invasibility, and create more complex null assumptions to compare against invader evolution within biological communities.

Introgression in the Anthropocene: detecting gene flow between native and alien flowering plants in the British flora

Lu M¹, Ruhsam M², Twyford A^{2,3}, Hollingsworth P², Thomas C¹, Martin S³, Dasmahapatra K¹

¹Leverhulme Centre for Anthropocene Biodiversity, Department of Biology, University of York, ²The Royal Botanic Garden Edinburgh, ³Institute of Ecology and Evolution, The University of Edinburgh

POSTER SESSION 1 - P01.052, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Human activities have altered species distributions drastically, and such changes often break down previous eco-geographical isolation between species, facilitating hybridisation between native and alien taxa newly brought into contact. Human-induced hybridisation can lead to contrasting evolutionary outcomes, ranging from the extinction of rare native taxa by demographic and genetic swamping, to the transfer of beneficial alleles that may assist local adaptation. Despite the fact that previous studies have evaluated introgression between native and alien taxa in a few illustrative cases, we still lack a holistic view on the prevalence and consequences of introgression across multiple taxonomic lineages. To address this knowledge gap, we present the first comparative study of human-induced introgression across multiple lineages of flowering plants at a floristic scale.

Based on floristic records, we target 88 known hybridising species-pairs that involve

a native and an alien plant taxon in the UK. Leveraging reference genomes from the Darwin Tree of Life project, we will generate whole-genome resequencing data to detect introgression using f-branch statistics and locate introgressed regions with window-based fdm scans. We will further test the adaptive value of introgressed regions by detecting signals of recent/ongoing selective sweeps. Finally, by integrating ecological and taxonomic trait data with the results of our genomic introgression estimates, we will develop a statistical model (MCMCglmm) to assess whether certain traits are associated with the extent of introgression.

This study will provide invaluable insight into the frequency, predictability, and evolutionary outcomes of gene flow between alien and native taxa at a floristic scale. The resulting statistical model will not only enable comparisons across diverse lineages for temperate floras, but may also help detect cryptic introgression.

Investigating morphological and behavioral spatial sorting in a predatory snake across a rapidly expanding invasion gradient

Vez M^{1,2}, Casbas G^{1,2}, Llargués Armesto M², Colomar V³, Lapiedra O¹

¹CREAF, ²Autonomous University of Barcelona (UAB), ³COFIB

POSTER SESSION 1 - P01.058, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biological invasions offer exceptional opportunities to study rapid trait divergence. An intriguing process potentially underlying such divergence is spatial sorting, where individuals with higher dispersal tendencies tend to accumulate at the expanding front, leading to non-random trait distributions. Over time, this can result in actual shifts in allele frequencies across their invasive range. This rapid evolution could enhance spread speed with every generation. The recent invasion of the horseshoe whip snake (*Hemorrhois hippocrepis*) on the island of Ibiza (Spain) provides a compelling case to study this intriguing evolutionary process. Introduced around 2003, this top predator rapidly colonized much of the island, driving rapid local extirpation of the island's native fauna, including the endemic Ibiza wall lizard (*Podarcis pityusensis*). Here, we examine spatial sorting by examining whether the invading snake population is undergoing shifts in morphology and behavior between the front of invasion (the expanding edge) and the core of invasion (the oldest established area). Using an extensive field dataset—including an unprecedented sample size for a vertebrate predator—we

focus on ecologically relevant traits related to dispersal and foraging, including boldness, exploration, refuge use, and body shape. Despite their likely evolutionary relevance, behavioral traits remain largely understudied in invasion biology. By integrating them with morphological data, we gain a deeper understanding of the mechanisms underlying phenotypic divergence across the invasive range. We report differences in the morphology and behavior of snakes from the front of invasion compared to those from the core, which may be linked to variations in prey consumption and movement strategies. These patterns, observed along a clear core-to-front invasion gradient and over a remarkably short timescale, provide rare insight into how rapid phenotypic shifts emerge during the early stages of invasion. Our results contribute to shed light into our understanding of how invasive species can rapidly evolve after successfully becoming established in new environment, a crucial open question for global biodiversity conservation given that predator-driven invasions are the leading cause of island extinctions worldwide.

Maternal care thwarts parasitoids in the invasive brown widow spider (*Latrodectus geometricus*)

Arabesky V¹, Johnson A¹, Rozenberg T¹, Lubin Y¹, Segoli M¹, **Mowery M**²

¹Ben-Gurion University of the Negev, Sede Boqer campus, ²City University Of New York, York College

POSTER SESSION 1 - P01.056, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Maternal care can maximize offspring survival and may contribute to the establishment success of invasive species. The brown widow spider, *Latrodectus geometricus*, is a successful invader worldwide. Here, we investigated the role of maternal care in enhancing its success. We compared the defence mechanisms of the invasive *L. geometricus* with those of another widow spider native to the Negev desert, *L. pallidus*, against an egg sac parasitoid wasp. Both spider species exhibited guarding behaviours following exposure to wasps; however, only *L. geometricus* efficiently evaded and successfully killed the parasitoid. Accordingly, its egg sacs were parasitized less frequently than those of *L.*

pallidus. Next, we evaluated the defensive role of the silk spike-like structures on *L. geometricus* egg sacs. When spikes were removed from half of the egg sac surface, the wasps laid more eggs on the spike-free side. In an additional experiment, *L. geometricus* females increased spike density on subsequent egg sacs after exposure to the parasitoid. We showed that *L. geometricus* employs both behavioural defences and modifications to the egg sac structure to protect against the parasitoid. These defences may provide *L. geometricus* an advantage over native species in its invasive range, potentially contributing to its invasion success.

Model-based demographic inference of recent invasions from genomic data

Campuzano Jiménez F¹, Zwaenepoel A¹, De Keyzer E¹, Svoldal H¹

¹Department of Biology, University of Antwerp

POSTER SESSION 1 - P01.065, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Invasive species are a major threat to biodiversity and a central topic in evolutionary biology. Biological invasions can be viewed as large-scale, unplanned experiments on how populations evolve to adapt to novel environments. However, in order to fully understand the evolutionary dynamics of invasions, it is essential to develop statistical tools that can disentangle the effect of selection and demographic processes in genetic variation.

In this work, we focus on the study of very recent invasions (that occurred less than 100 generations ago) using genomic data. More specifically, we aim to reconstruct the recent change in effective population size (N_e). Accurate estimates of N_e inform about the evolutionary history of a population and can guide conservation management plans, for example, by identifying the time of invasion and the rate of population growth. However, we found that the existing general-purpose methods that use linkage-disequilibrium (LD) and identity-by-descent (IBD) data have important limitations when

applied to realistic recent invasion scenarios.

We conducted extensive simulations to evaluate the limitations in the current methods and develop a novel approach specifically tailored to recent invasions that overcomes some of the observed issues. Our approach leverages coalescent theory to estimate key aspects of the invasion history from LD data and it is suitable for datasets comprising unphased genetic information from dozens to hundreds of individuals. Together with IBD data, we found that the estimated N_e trajectories can be used as a baseline to identify regions under recent positive selection. Moreover, we explored how approximate Bayesian computation methods based on IBD data can be used to study the dynamics of multiple spatial or temporal introductions. This work highlights the potential and limitations of demographic inference in the context of recent invasions and contributes to the development of tools for understanding rapid evolutionary processes in natural populations.

Phylogenomics and Trait Evolution in *Kalanchoe* (Crassulaceae): Insights from Whole-Genome Sequencing and Hybridization Analyses

POSTER SESSION 1 - P01.066, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Kalanchoe (Crassulaceae) is a diverse genus comprising nearly 200 species, predominantly endemic to Madagascar, with others distributed across continental Africa and parts of Asia. Despite its ecological and economic significance—ranging from horticulture to model systems for Crassulacean Acid Metabolism (CAM) photosynthesis and invasion biology—trait evolution and a stable phylogenetic framework accounting for reticulate evolution for *Kalanchoe* remain unresolved. To address these gaps, we present the most comprehensive phylogenomic analysis of *Kalanchoe* to date. We leveraged de novo whole-genome sequencing for 59 taxa, supplemented by 48 newly generated internal transcribed spacer (ITS) sequences and publicly available data. This yielded nuclear low-copy genes, plastomes, and ITS datasets for 90, 94, and 251 taxa, respectively. Phylogenetic inference based on these datasets revealed topological incongruences and high discordance, prompting further investigations into polyploidy and hybridization. Using ploidy

estimation from gene recovery, as well as parsimony, maximum likelihood, and Bayesian approaches, we identified several ancient allopolyploidization events across five subgenera, some of which coincide with reduced reliance on sexual reproduction. Our trait evolution analyses further elucidate the origins and diversification of *Kalanchoe*'s asexual reproduction modes. Four specialized clonal propagation strategies—virtually unique to the genus—evolved independently in monophyletic Malagasy lineages, whereas others exhibit convergent evolution or ancestral retention. Reversals in specialization suggest trade-offs between clonal and sexual reproduction. Additionally, biogeographic reconstructions support Madagascar as the ancestral range of *Kalanchoe*, with a single dispersal event out of Madagascar and two independent expansions into Asia via North-East Africa. This study highlights the power of phylogenomics in resolving complex evolutionary histories and underscores the role of hybridization and polyploidy in shaping trait evolution in *Kalanchoe*.

Reconstructing the Origins of Contrasting Colonization Events in *Littorina saxatilis*

POSTER SESSION 1 - P01.057, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In the current context of rapid environmental changes and increasing anthropogenic impact, understanding the evolutionary mechanisms underlying the uneven distribution of biodiversity is crucial to predict the redistribution of species, particularly why some populations are struggling to survive and/or adapt to changing environments, while others persist and even expand beyond their native range. To clarify how historical and genetic factors can drive colonization events, we analyzed available whole genome resequencing data from 475 *Littorina saxatilis* individuals collected from all over the North Atlantic region. This marine gastropod provides a powerful natural experiment of repeated colonization events across diverse environments, involving both recent and older range expansions, as well as some successful and some failing ones. We focused on the source of two range shifts: a failing recent introduction in the Venetian Lagoon (Mediterranean Sea, Italy), where the species represented the first confirmed alien species but is facing local extinction, and a successfully established colonization in Bodø, which has been settled there since the post-glacial range expansion in northern Norway. We investigated the origin of these two target populations, conducting analyses to reconstruct and clarify the colonization

routes and to compare genetic diversity between native and introduced populations. We observed that the south-eastern coast of England - particularly a lagoon area on the Norfolk coast - and possibly Mölle (Sweden) may have served as the source of the variability observed in the Venetian population, while Bodø most likely originated from a northward colonization by populations from the southern Norwegian coast or eastern UK populations. The 'stepping-stone' colonization pattern observed in Norway may have facilitated the successful establishment in Bodø, unlike the Venice population, which does not show evidence of intermediate stepping-stone populations - except potentially a lagoon population like Dersingham on the Norfolk coast. Interestingly, a long-distance dispersal hypothesis has also been considered for the Venetian population, proposing that its introduction might have occurred via maritime traffic or even through migratory birds acting as vectors. Our results enhance the evolutionary understanding of biological invasions and range shifts in *L. saxatilis*, help predict colonization outcomes, and allow us to draw conclusions about evolutionary dynamics that distinguish successful from failing range shifts, as well as local adaptation to new environments.

The Genomic Basis of Success and Failure in Marine Snail Range Expansions

Biello R¹, Sammarco B¹, Carmelet Rescan D², Bosso L³, Butlin R^{4,5}, Johannesson K⁵, Blakeslee A⁶, Westram A^{7,8}, Han B⁷, Mizzan L⁹, Magalhães M¹⁰, De Faria R¹⁰, Locatello L², Chang A¹¹, Benazzo A¹, Raffini F²

⁵University of Gothenburg, Tjärnö Marine Station, ⁶East Carolina University, ⁷Nord University, ⁸Institute of Science and Technology Austria, ⁹Museum of Natural History of Venice, ¹⁰CIBIO/InBIO, Research Center on Biodiversity and Genetic Resources, University of Porto, ¹¹Smithsonian Environmental Research Center

POSTER SESSION 1 - P01.059, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Anthropogenic disturbances and climate change are dramatically altering species distributions, yet the mechanisms determining why some populations successfully expand their ranges while others fail remain unresolved. We address this fundamental question using the marine snail *Littorina saxatilis*, which exhibits repeated natural colonization events, both successful and failed, across diverse environments. Our main goal is to uncover the mechanisms underlying successful versus failed colonisations in this species, clarifying the evolutionary forces that drive range expansion or contraction. Our study integrates 380 newly sequenced samples from previously unstudied areas (including introduced populations), combined with 420 existing genomes to create a comprehensive dataset of 800 individuals. By combining whole-genome resequencing data (SNPs

and structural variants), phenotypic trait variation, demographic modelling and fine-scale environmental data, we aim to: (1) identify signatures of diversity loss, genetic load, and local adaptation; (2) assess how demographic history, genomic architecture, and recombination rates shape selection efficiency; and (3) determine whether evolutionary background, chromosomal rearrangements, and adaptive traits predict colonization success. Our findings will provide novel insights into the evolutionary mechanisms that facilitate or constrain range shifts in response to environmental change. Moreover, this work will advance our understanding of biodiversity dynamics and have critical implications for predicting species responses to ongoing global change, informing more effective wildlife management strategies.

Transcriptomic Evidence for Enhanced Gut Function in Non-Native House Sparrows

McCain K¹, Kohl K², Schrey A³, Martin L¹

¹University South Florida, ²University of Pittsburgh, ³Georgia Southern University

POSTER SESSION 1 - P01.064, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Range expansions and biological invasions serve as powerful natural experiments for examining how organisms respond to novel ecological pressures. The house sparrow (*Passer domesticus*), one of the world's most widespread and successful invaders, provides an ideal system to explore how changes in gene expression supports individual survival and persistence in newly colonized habitats. As organisms expand into new environments, they encounter novel food resources, but food consumption carries inherent risks, particularly the potential for exposure to parasites. To mitigate these risks, we hypothesized that invaders likely have specific physiological mechanisms that promote gut resilience in the face of pathogen exposure.

We conducted mRNA sequencing on duodenal tissue from 24 adult male sparrows across four native and four non-native populations. A differential gene expression analysis identified 558 genes with significant expression differences between population types, with 232 upregulated and 326 downregulated in non-native sparrows. Notably, the majority of the genes significantly up-regulated in non-natives are involved in processes supporting gut integrity, namely epithelial turnover, cytoskeletal modifications, and cellular anchoring. These functions are critical for maintaining barrier structure, enhancing nutrient absorption, and preventing microbial invasion. These results support the idea that non-native sparrows exhibit physiological shifts that promote gut resilience, helping them manage the risks associated with novel ecological conditions.

Transgenerational Effects of Sublethal Insecticides in the Colorado Potato Beetles

Margus A¹, Kankare M¹, Tikka S¹, Karvanen J¹, Lindström L¹

¹University Of Jyväskylä

POSTER SESSION 1 - P01.060, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The evolution of insecticide resistance in the pest species has historically been attributed to strong directional selection from lethal insecticide concentrations. However, emerging evidence suggests that sublethal doses may also drive resistance through the hormetic effects. Our previous research demonstrated that

transgenerational exposure to sublethal doses in the invasive Colorado potato beetle induces hormetic responses, including increased larva-to-adult survival, adult body mass, and egg hatching. We further investigated the pesticide effects at the transcriptome level to identify mechanisms behind these transgenerational hormetic changes. Sublethal insecticide doses affected only a small fraction of genes (approximately 0.1%), with minimal overlap between low- and high-dose groups. Low-

dose exposure influenced metabolism, reproduction, and detoxification pathways, while high-dose exposure induced mostly stress-related responses. Surprisingly, offspring from both parental exposure groups showed increased survival across generations. However, gene expression patterns diverged: the low-dose group displayed greater variation in the expression patterns, whereas high-dose group individuals were more consistent, suggesting stronger selective pressure. To conclude, individuals exposed to sublethal insecticide doses can produce offspring with increased insecticide tolerance, likely mediated through various pathways depending on the exposure level. These findings highlight the complex dynamics of insecticide resistance and the potential role of hormetic effects in pest management strategies.

Urbanization and the Evolution of Stoichiometric Flexibility in Trinidadian Guppies

Amaral J¹, Mohamed A¹, Rigdon T¹, Gordon S¹, Lópes-Sepulcre A¹

¹Department of Ecology and Evolutionary Biology

POSTER SESSION 1 - P01.067, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Urbanization alters nutrient cycling and energy flow in freshwater systems, creating novel environments that impose strong selective pressures on resident organisms. One of these pressures is eutrophication, an increase in nutrient load; yet, we know little about how urban organisms adapt to this increased nutrient content. We address this gap by investigating the evolution of stoichiometric flexibility, the ability to regulate body elemental composition in response to nutrient availability, in urban and non-urban populations of guppies (*Poecilia reticulata*). We hypothesize that urbanization selects for greater stoichiometric flexibility, allowing individuals from highly urbanized environments to capitalize on eutrophication by adjusting their body elemental composition to nutrient availability. We predict that urban fish will show stronger stoichiometric shifts under nutrient-rich conditions. In contrast, less urban fish will maintain more stable ratios and growth under nutrient-poor conditions, reflecting divergent plastic responses shaped by urban environmental pressures.

To test these predictions, we maintained, under controlled conditions, 144 F2 female guppies originating from wild populations across two rivers in Trinidad (Maracas and Tacarigua) and two urbanization origins (high- "HU" and low-urbanization "LU"). We

fed them with one of two artificial diets differing in nutrient content ("high-" and "low-quality") for 7 weeks. Females were then presented to males for five days and left alone for 4 weeks. We then quantified the nutrient allocation towards body and reproductive tissues (C:N, C:P, N:P), as well as fish growth rate before and after male introductions.

Fish from HU sites, especially those from the Tacarigua river, exhibited distinct elemental composition with lower C:N ratios, consistent with greater %N and potentially enhanced stoichiometric flexibility. In contrast, low-urbanization fish maintained more stable elemental profiles regardless of food quality, suggesting reduced responsiveness to nutrient enrichment. Although all fish showed increased %C and higher C:N when fed high-quality food, the response was not significantly different between origins, indicating similar flexibility in carbon allocation.

By integrating controlled experiments with stoichiometric, we aim to uncover the mechanistic basis of urban evolution in fish. Ultimately, this work will advance our understanding of evolutionary processes in urban ecosystems and highlight the importance of organism stoichiometry in shaping their success in rapidly changing environments.

A genomically informed prediction of the overwintering range of cotton bollworm in North America

Williams C^{1,2}, North H^{1,3}, Jiggins C^{1,4}

¹Department Of Zoology, University Of Cambridge, ²Selwyn College, University of Cambridge, ³Girton College, University of Cambridge, ⁴St John's College, University of Cambridge

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

Species distribution models (SDMs) are widely used in invasion biology to identify suitable habitat and predict where an invasive species might spread after introduction. A key limitation of existing SDM methods is their assumption of niche uniformity throughout a species' range, with no consideration of evolutionary adaptation to local environmental conditions. This can lead to uninformative or potentially misleading predictions. As high-throughput DNA sequencing has become cheaper and more accessible, interest has grown in developing better SDMs that incorporate information about local adaptation from population genomic data. We leverage whole-genome resequencing data from over 1500 individuals to create genomically informed predictions of the present and future overwintering range of an invasive crop pest in North America, accounting for local adaptation.

The cotton bollworm *Helicoverpa armigera* is one of the world's most economically damaging agricultural pests. In its native range, it is widely distributed across Africa, Eurasia, and Australia, but is also invasive in South America. Of particular concern is a recently established population at Chicago

O'Hare Airport, which has the potential to spread throughout North America. We demonstrate that the recently established North American population carries a structural variant on the Z chromosome, which is locally adapted to warm winter conditions in *H. armigera*'s native range. We use this information to create a genomically informed SDM to assess habitat suitability across North America in the present and under future climate change. We find that incorporating genomic information about local adaptation decreases predictions of habitat suitability for *H. armigera* in North America, but that short-term climate change increases its risk of spread from Chicago regardless of local adaptation.

This research has resulted in a more refined assessment of at-risk areas from this invasive crop pest, with implications for agricultural management practices both now and in the future. Additionally, our methodology represents a novel and robust way of creating evolutionarily informed SDMs by explicitly incorporating information about local adaptation from population genomic data.

Bidirectional exchange of resistance genes between native *Helicoverpa zea* and invasive *H. armigera*

North H¹, Amado D¹, Montejo-Kovacevich G^{1,3}, Jiggins C¹, Soares Correa A²

¹University of Cambridge, ²Escola Superior de Agricultura Luiz de Queiroz, Universidade de São Paulo,

³Uppsala University

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

Invasive species pose significant threats to biodiversity and food security. Though regrettable, they also present remarkable evolutionary experiments. Population genomic data are increasingly being used to study biological invasion to quantify rapid adaptation in 'real time', while simultaneously informing efforts to monitor, manage and mitigate invasive pests. Noctuid moths of the genus *Helicoverpa* are among the most economically damaging crop pests globally. The invasive species *Helicoverpa armigera* was first officially reported in Brazil in 2012. There, it hybridized with its native sister species *H. zea*. We generated a 10-year time-series dataset spanning the course of the biological invasion. These data consist of over 1000 whole genome sequences from

Helicoverpa samples collected at 10 locations throughout Brazil. Although interspecific hybridization was rare due to pre- and post-zygotic reproductive barriers, occasional hybridization was sufficient to result in substantial inter-specific gene flow. Through adaptive introgression, synthetic pesticide resistance alleles were introduced to native *H. zea* from invasive *H. armigera*. More recently, alleles conferring resistance to Bt crops were introduced to invasive *H. armigera* from native *H. zea*. Despite the stability of species boundaries in sympatry, this exchange of fitness-enhancing alleles resulted in rapid adaptation over ecological time-scales, contributing to the spread of both pest species.

Invasion dynamics of the house mouse in Africa

Poveda Martinez D^{1,2}, Rougeron V^{3,4}, Brouat C^{1,2}, Prugnole F^{3,4}

¹Centre de Biologie pour la Gestion des Populations (CBGP), ²Institut de recherche pour le développement (IRD), ³REHABS, International Research Laboratory, CNRS-NMU-UCBL, George Campus, Nelson Mandela University, ⁴Sustainability Research Unit, George Campus, Nelson Mandela University

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

The house mouse (*Mus musculus domesticus*), a commensal rodent, has become one of the most widespread and successful invasive mammals worldwide. Its range expansion has closely followed human migration patterns, first during Antiquity and later during European colonial expansion. While genomic studies have uncovered significant insights into the colonization patterns of *M. m. domesticus* across Europe, North America, and oceanic islands, its invasion history in Africa has remained largely unexplored, despite Africa's central role in human trade and migration. In this study, we present a large-scale population genomic analysis based on 416 whole-genome sequences, including 333 new genomes from 13 African populations. Through genome-wide genetic population analyses and demographic reconstruction, we uncover evidence for at least three independent colonization events into Africa from distinct Eurasian sources. North African populations (Morocco, Algeria) and Niger show genetic ancestry tracing back to the Iberian Peninsula; Tunisian populations are linked to Eastern Mediterranean ones; and populations from West and Central Africa

(Senegal, Mali, Gabon, and Benin) cluster with Northern European lineages. Our analyses also reveal signals of introgression from the native *Mus spretus*, especially in regions of current sympatry such as Tunisia and Morocco. These introgression signals gradually decline from north to south within Africa. Demographic analyses suggest severe bottlenecks associated with each colonization wave. The timing of these events aligns with known historical human movements: ~800 years ago in North Africa, and ~200–600 years ago in West Africa, the latter being consistent with colonial-era introductions. Overall, our findings reveal a complex history of *M. m. domesticus* in Africa, shaped by multiple introduction events in different areas, hybridization with native species, and the signature of human-mediated dispersal. By incorporating a dense genomic sampling across Africa, our study fills a major gap in the global invasion history of *M. m. domesticus*. We provide the final missing piece of the puzzle, positioning Africa as a crucial region in understanding the evolutionary dynamics and human-mediated dispersal of this commensal species.

Rapid adaptation in an island endemic lizard in response to an invasive predator?

Talavera A¹, Casbas G¹, Vez M¹, Amor-Jiménez C¹, Giska I¹, Lapiedra O¹

¹CREAF (Centre for Ecological Research and Forestry Applications)

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

Evolution is most often envisaged as a slow-paced phenomenon, and its study is therefore usually restricted to long time-scale comparisons. However, research on evolutionary biology has witnessed a recent paradigm shift: the Anthropocene has shown us that evolution is not only a gradual, slow process, as Darwin had hypothesized. Instead, human-induced rapid environmental changes have helped us understand that evolution can in fact happen in contemporary timescales, with biological invasions being one of the major drivers of evolutionary shifts.

Whereas rapid adaptation of invasive species to new environments has received increased attention, the extent to which native species may adapt to their invasive predators remains largely unexplored. By

leveraging an ongoing invasion of horseshoe whip snakes (*Hemorrhois hippocrepis*) in the island of Ibiza (Spain), we assessed the evolutionary response of their most common native prey, the Ibiza wall lizard (*Podarcis pityusensis*), a well-known example of island tameness. Using X-rays and newly designed behavioral assays, coupled with Whole Genome Sequencing data from over 300 individuals of this endangered lizard, we examined: 1) morphological and behavioral shifts throughout the snake invasion, 2) candidate SNPs associated with those changes, and 3) the presence of detectable selection signatures in response to the invasion. Our study provides valuable insights into how island endemic species can adapt facing dramatic predation regime shifts.

Short and long term effects of an invasive parasite on the physiology of host fish populations.

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

Homogenisation of communities, loss of genetic structure and decline or extinction of endemic species are some major threats presented through the spread of invasive species. Invasive parasites pose an acute challenge to native hosts. *Sinanodonta woodiana*, an invasive freshwater mussel from East Asia, has exhibited an explosive global spread including many European water bodies. *S. woodiana* has a generalist parasitic larval stage (glochidium), taking advantage of naïve European fish hosts including the European bitterling, *Rhodeus amarus*. *R. amarus* is a native European cyprinid fish that exhibits an intimate reciprocal relationship with unionid mussels. Bitterlings spend most of their lives in close proximity to mussels as a result of their unusual reproductive biology when they lay their eggs into mussels' gills. Bitterlings coevolve with native mussel partners and are able to minimize the infection of mussel glochidia. Glochidia decrease the physiological state of their fish hosts and the invasion by *S. woodiana* presents a new challenge to European bitterlings compared to native unionids. Our study included three populations of bitterling with varying levels of sympatry with *S. woodiana* to test the role of rapid coevolutionary response in terms of host defence and the impact of the invasive

parasite on physiological state of *R. amarus* individuals. Using experimental infections, we measured short-term (immediate survival and swimming capacity) and long-term (overwintering survival, growth rate, and condition) impacts on host physiology. Our study demonstrates a significant difference in short-term and long-term effects of *S. woodiana* glochidia on *R. amarus*. Compared to control fish, parasitised fish showed lower survival and swimming performance immediately after infection. The only population difference was observed in the number of glochidia attached on the fish, where the population with longest sympatry with *S. woodiana* had the least glochidia attached. In contrast to these findings, surviving *R. amarus* seemed to be generally unaffected by the parasitic infection later in their life, in terms of overwinter survival, physiological condition, reproductive allotment and growth rate. Overall, we did not observe a clear population specific role of rapid coevolution but a significant impact on short term survival and swimming performance. The lack of negative impacts in the long-term consequences of glochidia parasitism could be a result of higher mortality of infected fish in early stages, and hence eliminating weaker individuals (selective disappearance).

Unusual genetic structure of the alien plant *Cotula coronopifolia* in Europe, resulting from selfing, introduction history and dispersal by migratory waterbirds

MEETING ROOM 120+121, August 18, 2025, 10:30 AM - 12:30 PM

Migratory waterbirds play a significant role in the long-distance dispersal (LDD) of plants lacking fleshy fruits. However, their influence on the spread and genetic connectivity in invasive species remains poorly understood. We selected for our study the buttonweed *Cotula coronopifolia*, a species native to South Africa and introduced into Europe over two centuries ago. Although the species is predominantly coastal, it is expanding inland in Sweden and the UK. Faecal analysis supports dispersal by waterbirds as a key role for spread since the initial introduction to Europe in the 18th century. However, it is also commercially available as a pond plant.

We selected a total of 26 populations of *C. coronopifolia* across six European countries (Sweden, Germany, Netherlands, UK, Portugal and Spain) and four populations within its native range in South Africa. Genotyping by sequencing (GBS) was conducted on 266 individuals, generating extensive sequence and single nucleotide polymorphism (SNP) data. We estimated the genetic variability of populations and evaluated their genetic structure using the Bayesian clustering method implemented in the program STRUCTURE. We used STAIRWAY PLOT to infer the demographic trajectories of the different genetic clusters (=lineages) identified by STRUCTURE analyses and BPP to reconstruct their phylogenetic relationships and estimate divergence times.

Our results show the presence of three main lineages across the invaded range in Europe, whereas each population sampled within the native range in South Africa formed its own genetic cluster. Some individuals and populations show signals of admixture among different genetic clusters, which often translates into higher levels of genetic diversity. However, an initial increase of genetic diversity following admixture

seems to be erased after a few generations due to the predominantly selfing nature of the species. Phylogenetic analyses revealed that one population from South Africa diverged from a clade comprising all other lineages during the last glacial period (ca. 40 ka BP). This clade then split almost simultaneously into four lineages around the Last Glacial Maximum (ca. 23ka), followed by the divergence of two lineages currently restricted to the invaded range in Europe during the Middle Holocene (ca. 6 ka BP). Demographic reconstructions indicate that effective population sizes of European populations have remained constant since the documented arrival of the species to the continent (1739). Native populations exhibit idiosyncratic demographic trajectories and have experienced declines, expansions or bottlenecks since the onset of the Holocene.

Our analyses indicate a predominantly self-crossing nature of *C. coronopifolia*, which results in very limited admixture among genetic clusters and extremely low levels of genetic diversity. Estimation of divergence times suggests that multiple introductions may have occurred, likely facilitating the establishment and spread of the species in Europe. Sharing of clusters between coastal and inland sites connected by waterbirds as well as the presence of three genetic clusters in the Netherlands, which function as a nexus between other countries in migratory flyways, support the potential role of waterbirds in the spread of the species. Alternative hypotheses that were not supported include a higher connectivity between populations connected by ocean currents, which would be expected under sea dispersal, and higher diversity near major urban centres or ports, as would be expected under repeated contemporary introductions through shipping or horticulture.

Evolution of Mutational Susceptibility to Genetic Diseases

Kelly M¹, Weghorn D¹

¹Centre For Genomic Regulation (CRG)

POSTER SESSION 3 - **P03.016**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Cancer is a genetic disease, remnant from a time before multicellularity, when individual cells prioritised their own growth over cooperative constraints. Major efforts in cancer genomics have focused on identifying cancer driver genes that can cause cancer when mutated. While extensive research has focused on how cancer is controlled once mutations arise in these genes, it remains unknown whether natural selection has also acted on the root cause: the probability of these mutations occurring in the first place. We are quantifying how mutation probabilities in cancer driver genes have evolved by reconstructing ancestral genomes across the primate and mammalian phylogenies. Focusing on key COSMIC mutational signatures SBS1 and SBS5, we find a decrease in susceptibility to

these processes from the human-gibbon common ancestor to modern humans. To distinguish cancer-specific selection from neutral evolutionary drift, we apply a fine-tuned model of neutral evolution. We further expand our analysis to investigate the broader question of mutational bias in germline processes for genes under varying germline selection pressures. This work introduces a new framework for understanding how mutational processes shape cancer risk and how germline evolution influences susceptibility to genetic diseases. It will further shed new light on Peto's paradox and may ultimately contribute to advancements in cancer prevention, early detection, and therapeutic strategies.

Intra-tumor evolution can favour inter-clonal cooperation and facilitate metastasis

Carneiro C, Nedelcu A

¹University Of New Brunswick

POSTER SESSION 3 - **P03.184**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Tumours are genetically and phenotypically diverse populations of clones that can also exhibit high levels of phenotypic plasticity in response to both microenvironmental cues and signals from each other or other non-cancer cells. This tumour complexity reflects in multifaceted evolutionary dynamics that ultimately result in increased individual fitness or collective success. Nevertheless, we are just starting to understand the implications of these phenomena. While inter-clonal competition may result in selective sweeps and a reduction in heterogeneity, recent findings indicate that cancer clones can also participate in cooperative interactions, which could contribute to maintaining tumor heterogeneity. Recently, we have addressed the role of inter-clonal cooperation in increasing the metastatic potential of tumours. Specifically, to investigate if and how genetically diverse clones cooperate during migration and invasion, we used distinct cancer cell lines expressing different metastatic capabilities. We found that the conditioned media from highly invasive cancer lines (breast and lung) enhanced the migration and invasion of less metastatic lines. This inter-clonal cooperation involved the transforming growth factor $\beta 1$ (TGF- $\beta 1$) signaling pathway. Moreover, co-culturing a less aggressive line with a highly metastatic breast line enhanced the invasive potential of both lines, facilitated by the co-option of the weakly metastatic clone into expressing an enhanced malignant phenotype that benefited both clones (i.e., a "help me help you" strategy). Based on our findings, we proposed a model in which crosstalk, co-option, and co-dependency can facilitate the evolution of synergistic cooperative interactions between genetically distant clones. Specifically, we suggest that synergistic cooperative interactions can easily emerge between genetically distant clones via crosstalk involving clones able to constitutively secrete molecules that induce and maintain their own malignant state (producer-responder clones) and clones that can respond to those signals (responder clones) and express a metastatic behaviour. Our findings also suggest that interfering with such cooperative interactions during the early steps in the metastatic cascade could provide additional strategies to increase patient survival. However, therapies targeting inter-clonal cooperation remain underexplored. Given that TGF- $\beta 1$ can transactivate the epidermal growth factor (EGF) signaling pathway, we investigated the potential of inhibiting the EGF receptors (EGFR) as a therapeutic intervention. We found that treatment with approved EGFR inhibitor drugs significantly reduced migration and invasion in both cell lines. To elucidate the molecular mechanisms underlying this cooperative interaction and identify additional genes that can be targeted therapeutically, we conducted transcriptomic analyses to (i) identify genes and pathways regulated during this inter-clonal interaction and (ii) assess the impact of EGFR inhibition. Overall, these studies underscore the importance of deciphering the nature and mechanistic basis of inter-clonal cooperative interactions that could take place during cancer progression. This is particularly relevant to metastasis, for which treatment options are limited, despite the fact that it is responsible for most cancer-related deaths.

Investigating the metastatic potential of two transmissible cancers in Tasmanian devils

Pirard F^{1,2}, Glitho S^{2,3}, Thomas F², Kissa Marin K³, Ujvari B¹

¹Deakin University, ²CNRS, ³INSERM

POSTER SESSION 3 - **P03.196**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: The Tasmanian devil is one of the few species known to be affected by transmissible cancers, posing a critical threat to its survival. Two distinct cancers, Devil Facial Tumour Disease 1 (DFT1) and Devil Facial Tumour Disease 2 (DFT2), are transmitted through biting and have the unique ability to evade immune detection while spreading (metastasizing) within the host. Once established in a new host, these cancers can metastasize to internal organs, ultimately leading to organ failure and death. Despite their similar transmission routes, DFT1 and DFT2 differ in their rates of spread, proliferative and competitive capacity, within host tissue, and overall virulence. Remarkably, both cancers arose independently from Schwann cells, glial cells of the peripheral nervous system, approximately 30 years apart. This convergence in cellular origin within the same host species makes them an exceptional model for investigating tumour evolution, metastatic mechanisms, and tumour–microenvironment interactions. This study aims to: (1) Compare the metastatic potential of DFT1 and DFT2, (2) Assess their competitive interactions, (3) Investigate their communication with the tumour microenvironment, particularly macrophages and nerve cells.

Materials and Methods: An in vivo zebrafish embryo model was employed to study complex tumour–host interactions. Transgenic zebrafish lines with fluorescently labelled macrophages or neurons were transplanted with GFP-labelled DFT1 or DFT2 cells in the swim bladder. Proliferation, migration, and co-localisation were

monitored over four days using confocal and fluorescence microscopy. Images were analysed using ImageJ software.

Results: DFT2 cells showed high proliferation at the injection site within 24 hours and rapidly initiated migration into surrounding tissues. By day 2, cells were detected in multiple regions including the head, yolk sac, notochord, eye, kidney, and tail. These migrating cells often appeared in close proximity to both macrophages and neural tissue. In contrast, DFT1 displayed a delayed response, with limited proliferation during the first 48 hours and initial migration observed from day 3 onward. This suggests DFT2 may possess more intrinsic properties facilitating invasion and dissemination, or it may interact more effectively with the host microenvironment.

Conclusion: These early findings indicate that DFT2 exhibits a more aggressive metastatic phenotype compared to DFT1, aligning with previous in vitro studies. The use of a zebrafish model allows real-time visualization of tumour–host interactions, including proximity to macrophages and nerve structures, which may play a role in facilitating or constraining tumour spread. Ongoing analysis will explore how these interactions differ between DFT1 and DFT2, with a particular focus on neural tropism given both cancers' Schwann cell origins. This work may provide insights into the evolutionary pressures shaping tumour transmissibility and metastasis, with potential relevance to wildlife conservation but also human cancers involving nerve–tumour interactions.

No evidence that oestrogen positive breast cancer risk is genetically correlated with human life-history traits

Young E¹, Erten E¹, Postma E², Lumaa V³, van der Vegt B⁴, de Bock G⁴, **Dugdale H**¹

¹University of Groningen, ²University of Exeter, ³University of Turku, ⁴University Medical Center Groningen

POSTER SESSION 3 - P03.202, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Oestrogen positive breast cancer (ER+) is one of the most prevalent cancers, but the evolutionary processes shaping genetic variation in ER+ risk are poorly understood. Here, we explore evidence for antagonistic pleiotropy between ER+ risk and human life-history traits, testing whether increased genetic ER+ risk is indicative of a reproduction-survival trade-off or fast life history. We estimate genome-wide genetic correlations between ER+ risk and three life-history traits (the numbers of children born, and age at menarche and first birth) using genomic restricted maximum likelihood analyses on Lifelines biobank women, and – for the first time – perform linkage disequilibrium score regression on European family-based genome-wide association study data. Regardless of the data or method used, genetic correlations were low and not statistically different from zero. Thus, we find

no evidence for antagonistic pleiotropy between ER+ risk and life-history traits, suggesting that these mutations have instead accumulated due to weak selection at older ages. We cannot rule out antagonistic pleiotropy shaping the evolution of individual ER+ risk variants but, given these traits' polygenic nature, our quantitative genetic analyses are best placed to assess its genome-wide importance, which appears minimal. Our results also suggest, at most, only the smallest changes in prevalence of genetic ER+ risk in future generations due to natural selection but future studies should examine how this genetic variation interacts with numerous environmental risk factors. In a landscape of ageing demographics and anthropogenic changes, continued study of ER+ risk factors is vital in the fight against cancer and the promotion of healthy ageing.

Organ-specific variability of tumor prevalence across wild mammals

POSTER SESSION 3 - P03.191, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Cancer appears ubiquitous across the vertebrate's tree of life, yet susceptibility to this disease varies significantly among species, as for example mammalian orders exhibiting notably different cancer prevalences. Specifically, carnivorous species face higher cancer risk, potentially due to mutagens biomagnification, dietary composition, or pathogen-driven oncogenesis. In addition, many studies demonstrate a counterintuitive absence of associations between cancer risk and body mass or life expectancy, a phenomenon called Peto's paradox. However, it remains to be explored how cancer susceptibility in various organs scales with body mass or lifespan across species. Exploring this could also offer valuable insights into the evolution of cancer resistance mechanisms and clarify whether the previously demonstrated dietary influences on cancer risk are linked to organ-specific vulnerabilities or broader, systemic increases in cancer risk.

Materials and methods: To estimate tumor prevalence in different organs, we used medical data extracted from the Zoological Information Management System (Species360), providing a centralized international database of captive animals. We obtained 12,403 necropsy reports for 58 mammalian species, including 761 reports containing one or more neoplasia diagnosis, from which we extracted the organ affected by the tumors. Organs were gathered in 9 functional groups: lymphatic system, gastro-intestinal system, uro-genital system, skin, endocrine system, nervous system, respiratory system, circulatory system and fat tissues. Diet, body mass and life expectancy data were collected from the literature.

To assess tumor prevalence differences between phylogenetic orders, we estimated phylogenetic

signals for each group of organs, and performed pairwise order comparisons. When investigating diet effects, we used independent Phylogeny-corrected Generalized Linear Mixed Models (PGLMM) regressions. Each of the regressions were corrected by body mass and life expectancy. PGLMM regressions were also used to investigate Peto's paradox, using body mass or life expectancy as sole explanatory variables of tumor prevalence. All PGLMM regressions took into consideration the total number of necropsies available per species, as the tumor prevalence estimation is expected to be more precise with an increased number of necropsy records.

Results: We found a significant phylogenetic signal on tumor prevalence in the lymphatic system and the skin. Additionally, for the same two groups of organs, species in the Carnivora order show significantly higher tumor prevalences than those in Artiodactyla and Primates. When assessing the effect of diet on tumor prevalence for each group of organs, the consumption of Mammals as a primary or secondary food item was positively correlated with tumor prevalence in the lymphatic system, the GI system, the skin, and the endocrine system. Finally, for all groups of organs, no significant relationship was found between tumor prevalence and adult body mass or life expectancy.

Conclusions: Our results reveal that the increased risk of cancer observed for Carnivora in previous studies is more likely to be associated with a systemic increased risk of cancer, rather than only in the digestive system. Finally, as no relationship was found between tumor prevalence and body mass or life expectancy, Peto's paradox is validated at the scale of different organs, suggesting that the cancer resistance mechanisms evolved by bigger/longer-lived species are general to all organs across the body.

Pan-Mammalian genomic insights into cancer resistance and therapeutic target discovery

Padovani G¹, Smith L¹, Gilman N¹, Cahill J¹, Graim K¹

¹University of Florida

POSTER SESSION 3 - **P03.202**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Translating pre-clinical cancer discoveries into effective human treatments is particularly challenging, especially for rare cancers, which often lack enough patients to conduct clinical trials and build effective models. Comparative oncology leverages non-human animals to help model diseases such as cancer. However, identifying model organisms suitable for studying a particular disease can be difficult. For example, pre-clinical trials using the common mouse model have a 92% failure rate in Phase I trials. Utilizing mammals with higher clinical and genomic similarity to human diseases as non-traditional models, such as dog models of breast cancer and sarcomas, can yield more successful results and highlight the promise of comparative oncology. However, reliable identification of animal models most suitable for diseases such as cancer remains challenging. Suitable model organisms for a cancer will be those who share high genomic similarity with humans across genes associated with the given cancer. One way of identifying this genomic similarity is to analyze evolutionary information across

mammals. Here, we apply PhyloP across the Zoonomia 241 species alignment to identify conserved and accelerated regions across mammalian species and compare it to a null model with shuffled genomic information. Within each of the 19 Zoonomia orders, we do pairwise comparisons between species and perform enrichment analysis in human cancer genes by statistically evaluating PhyloP conservation and acceleration scores in all COSMIC cancer genes. We compare these scores to a randomly selected set of non-COSMIC cancer genes and repeat this comparison with replacement 100 times. This allows us to select the most enriched genes related to cancer in each species across the mammalian trees. From this, we identified pan-mammalian mechanisms of cancer resistance and susceptibility by analyzing the evolutionary history of cancer-related genes and pathways. Our results demonstrate that incorporating evolutionary information into model organism selection is a way to identify promising model organisms.

Preventing evolutionary rescue in cancer using two-strike therapy

Patil S^{1,2,3}, Ahmed A⁴, Viossat Y⁵, **Noble R**¹

¹City St George's, University of London, ²EMBL Heidelberg, ³Indian Institute of Science Education and Research, Pune, ⁴Johns Hopkins University, ⁵Université Paris-Dauphine

POSTER SESSION 3 - P03.199, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

First-line cancer treatment frequently fails due to initially rare therapeutic resistance. An important clinical question is then how to schedule subsequent treatments to maximize the probability of tumour eradication. I will present a theoretical solution to this problem obtained by using mathematical analysis and extensive stochastic simulations within the framework of evolutionary rescue theory. Whereas standard clinical practice is to wait for evidence of relapse, we confirm a recent hypothesis that the optimal time to switch to a second treatment is when the tumour is close to its minimum size before relapse, when it is likely undetectable. This optimum can lie slightly before or slightly after the

nadir, depending on tumour parameters. Given that this exact time point may be difficult to determine in practice, we have studied windows of high extinction probability that lie around the optimal switching point, showing that switching after the relapse has begun is typically better than switching too early. I will further reveal how treatment efficacy and tumour demographic and evolutionary parameters influence the predicted clinical outcome, and insights into how best to schedule drugs of unequal efficacy. Our work establishes a foundation for further experimental and clinical investigation of this evolutionarily-informed multi-strike treatment strategy.

The cross-talk between ER+ breast cancer cells during progression

Wierzbicka K¹

¹IRB Barcelona, University of Barcelona

*POSTER SESSION 3 - **P03.182**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

Metastasis to this day remains the primary cause of most breast cancer (BCa) related deaths. Estrogen receptor-positive (ER+) BCa shows a higher recurrence rate after five years of diagnosis than in the first five years. Regardless of the substantial research efforts, the exact mechanisms that allow cells to metastasise are still unclear. Recent studies indicate that metastases can arise from polyclonal seeding of multiple genetically distinct clones interacting with each other while they progress. Interestingly, both negative and positive interactions between those cells coincide, pointing out that cancer behaves according to concepts of evolutionary Game Theory, and should be

viewed as a living ecosystem. We aim to identify how stochastic the composition of those polyclonal clusters is in the context of ER+ BCa cells metastasising to the secondary organs, thus elucidating the cross-talk between those clones.

To study those processes, we use a variety of state-of-the-art techniques. We aim to trace each clone in vivo using multiple multicolour lineage tracing approaches and analyse the data with advanced microscopy, flow cytometry, single-cell RNA-seq and computational interaction analysis. Once cross-talk between the cells is identified, we will next focus on interrupting it to disrupt the metastatic progression process.

The role of the microbiome in transmissible cancers, a case study on Tasmanian devil facial tumour diseases

Jeanjean J¹, Oxley A¹, Telonis-Scott M¹, Thomas F², Hamede-Ross R³, Ujvari B¹

¹Deakin University, ²French National Centre for Scientific Research, ³University of Tasmania

POSTER SESSION 3 - **P03.187**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Tasmanian devil's (*Sarcophilus harrisii*) populations decreased by 80% over the last 40 years due to the emergence of two transmissible cancers, the Devil Facial Tumour 1 and 2 (DFT1 and DFT2). Currently, the Devil Facial Tumour Disease (DFTD), is present across more than 90% of Tasmania's territory. While extensive research has focused on the tumours' origin, evolution and disease epidemiology, since the discovery of the first cancer in 1996, the presence and impact of tumour and host microbiomes remain largely unexplored. In human cancer, microbes are known to influence cancer progression and therapeutic outcomes by affecting host immune responses to tumours. They have also been used as diagnostic markers for cancer development. We therefore propose that, similar to human cancers, the microbial communities may have a similar role and impact in DFTD. The aim of this project is to investigate interactions between the host, microbiome and tumour progression. First, opportunistically collected biopsy samples were used to characterise the microbiome of DFT1 and DFT2 tumours. By using a 16S amplicon sequencing approach the microbiome of a total of 50 DFT1/DFT2 tumour samples were analysed. Four times as many Amplicon Sequence Variants (ASVs), indicating a more diverse

microbiome community, was found in DFT2 than in DFT1 tumours. Investigating multiple tumours from the same devils also showed that the microbiomes of DFT1 tumours clustered together while the microbiome of DFT2 tumours were much more diverse. Next, the study will be focusing on identifying changes in asymptomatic and symptomatic Tasmanian devil gut microbiome over time to identify potential cancer biomarkers using faecal matter archived since 2012. Over 300 faeces samples, including more than 80 diseased devils, and some with several recaptures (including times where the individual was first confirmed disease-free and then later showing signs of tumour development) will be analysed. Full-length sequencing of the 16s and Internal Transcribed Spacer (ITS) genes, targeting the bacterial and fungal communities, are currently under way. The expected outcomes of this part of the project are the characterisation of the gut microbiome of asymptomatic and symptomatic devils along with the identification of potential markers of the cancer. The longitudinal samples will also allow for detecting changes in the microbiome along disease progression. Data analyses will be completed by August, and the results will be presented at the ESEB 2025 conference.

Using evolutionary accumulation models to identify therapeutic targets in cancer

Ríos-Arroyo Í^{1,2}, Johnston I^{3,4}, Idmbarek A^{1,2}, **Díaz-Uriarte R**^{1,2}

¹Universidad Autónoma de Madrid, ²Instituto de Investigaciones Biomédicas Sols-Morreale (IIBM), CSIC-UAM, ³Department of Mathematics, University of Bergen, ⁴Computational Biology Unit, University of Bergen

POSTER SESSION 3 - P03.024, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Cancer progression is caused by the sequential accumulation of somatic mutations during the life of an individual: cancer cells can accumulate mutations that increase cell-level fitness, increasing in frequency and spreading (and ultimately resulting in metastasis), at the expense of the whole organism.

Because of epistatic interactions, the accumulation of cancer mutations is often constrained to follow only some possible sequential orders, as the effect or viability of a mutation can depend on the presence of other mutations. Evolutionary accumulation models (EvAMs), also known as cancer progression models, have been developed to infer these dependencies in the order of accumulation of mutations during tumor progression. EvAMs use cross-sectional data and have been used in computational oncology, virology, and malaria progression. They have been applied to identify interactions between events, evolutionary routes of feature acquisition, and to improve patient stratification and survival prediction.

It has been suggested that EvAMs could be used to determine which genes to target by leveraging EvAMs' inferences about the evolutionary process. There is, however, no procedure in the literature for how to use EvAMs to this end, nor information on how EvAMs would perform.

Objectives, Approach, and Result: Here we explore the use of EvAMs to identify therapeutic targets. The focus is not on the quality of the inferences about the patterns of dependencies; instead, we want to know what could work from the point of view of interventions. We shift the focus from "correct" to "actionable" inferences. We define targeting a gene as making all genotypes that bear a mutation in that gene

lethal. This allows us to define a ground truth: for any fitness landscape, we can systematically examine the effects that targeting every gene has in terms of population composition. Then, given a specific objective (e.g., decrease the frequency of a particular genotype) we can rank how much targeting each gene contributes to this objective. Once we have the ground truth, we can assess EvAMs. An EvAM will be useful to identify targets if it can provide a ranking of gene interventions that is very similar to the true ranking of genes defined from the ground truth.

The protocol we use to identify the ground truth is an application of Pearl's do-operator, and our definition of effect is a simple rewording of Hernan and Robin's "causal effects in populations, that is, numerical quantities that measure changes in the distribution of an outcome under different interventions." To obtain the predictions under intervention from EvAMs, we show how to alter the fitted models so that they provide the counterfactual predictions under intervention; we discuss how to use a do-operator procedure under sensible modularity assumptions. We also address the difference between our definition of intervention ("making all genotypes that bear a mutation in that gene as lethal") and another intuitive definition of intervention as suppressing (or inactivating) the effects of a mutation. We show the performance of several state-of-the-art EvAMs under a simple strong selection, weak mutation model of evolution.

Conclusions: Our work highlights the opportunity to use EvAMs to identify therapeutic targets and the need to devise protocols to obtain explicitly causal predictions from these models, so they can be used in more complex evolutionary scenarios.

When rest fails, tumors rise: sleep-like state deprivation reveals an ancestral cancer-protective function in Hydra

Meliani J¹, Berriahi Z¹, Renard J¹, Asselin K^{1,3}, Tissot S¹, Thomas F¹, Dujon A^{1,2}

¹CREEC/MIVEGEC, Université de Montpellier, CNRS, IRD, ²School of Life and Environmental Sciences, Deakin University, Waurn Ponds, ³Université de Namur, Faculté de médecine, Unité de recherche en physiologie moléculaire (URPhyM)

POSTER SESSION 3 - **P03.204**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Sleep is a behavioral and physiological state shared across the tree of life, but its evolutionary origins and core functions remain unclear. While sleep has been primarily studied in organisms with centralized nervous systems, sleep-like states have also been identified in early-diverging animals such as Hydra, a freshwater cnidarian with a simple body plan and no centralized brain. Hydra exhibits periods of behavioral quiescence structured not by circadian cycles but by endogenous ultradian rhythms—internal activity cycles shorter than 24 hours. This positions Hydra as a unique model to investigate the ancestral, possibly non-neural, functions of sleep-like states in multicellular life. Using mechanical stimulation, we chronically disrupted the sleep-like state in several Hydra species and monitored its impact on tumor development, phenotypic traits, and life-history parameters. Our main model, Hydra oligactis, included genetically distinct strains with varying spontaneous tumor susceptibility, including a lineage carrying vertically transmitted tumors. To adopt an evolutionary perspective, we also included three other species—H. viridissima, H. circumcincta, and H. vulgaris—that are not known to develop tumors, allowing comparisons across phylogenetically diverse, tumor-resistant backgrounds. Our results show that sleep-like state deprivation induces a marked increase in tumor incidence in H. oligactis, with tumors progressively growing over time. No comparable tumor-related effects were observed in the other species. Importantly, we did not detect significant changes in

budding rate or tentacle number, suggesting that sleep-like state deprivation does not overtly disrupt these specific life history traits under the tested conditions. This indicates that the effects of sleep disruption may selectively target tumor-related cellular processes without broadly altering morphology or growth patterns. These findings suggest that the sleep-like state in Hydra contributes to the regulation of cell proliferation and the suppression of tumor formation, even in the absence of visible effects on classical life-history traits. The contrast between tumor-prone and non-tumor-prone species supports the hypothesis that one of the ancestral evolutionary roles of sleep-like behavior could have been to protect multicellular organisms from cellular dysregulation — particularly neoplasia — possibly through interactions with other co-evolved physiological processes. From an evolutionary perspective, our results suggest that the link between behavioral quiescence and cancer resistance predates the emergence of centralized nervous systems and may represent a deeply conserved function of sleep-like states. In an organism like Hydra, where regeneration and cell turnover are tightly regulated, the loss of behavioral rest appears to disrupt key mechanisms of somatic maintenance. By uncovering this link in a simple yet highly regenerative model, our study offers new insight into the evolutionary pressures that may have shaped the emergence of sleep — not merely as a neural necessity, but as a fundamental mechanism for preserving somatic integrity in early multicellular life.

An unexplored connection between mutation, phenotypic plasticity and evolutionary convergence in cancer

Nedelcu A¹

¹University Of New Brunswick

MEETING ROOM 122+123, August 22, 2025, 2:00 PM - 3:00 PM

All cancers are characterized by a series of shared phenotypic traits referred to as hallmarks of cancer. Because cancers that emerge and evolve independently within distinct individuals do not share a common ancestor (except for the few cases of transmissible cancers), the independent and recurrent expression of similar phenotypes (in the absence of similar patterns of genetic change or gene expression) suggests a high degree of convergence. Recently, unlocking phenotypic plasticity and nonmutation epigenetic reprogramming have been included in the list of emerging hallmarks and enabling characteristics of cancer. Generally, phenotypic plasticity can provide organisms a suite of adaptive traits in response to environmental changes. In addition, in multicellular organisms, individual cells can also express distinct stable or plastic phenotypes in response to developmental and microenvironmental cues. All cancers can independently access some of these normal cell phenotypes, and their expression in atypical contexts provides cancer cells with traits that increase their individual or collective success. Such phenotypes can be either stable (and heritable) or transitory (in response to specific signalling molecules from or microenvironmental stimuli). Nevertheless, the mechanisms underlying the plastic induction or stable expression of this unlocked plasticity are not well understood.

Building on our work on the evolution of multicellularity, I propose two new potential mechanisms that could contribute to the expression of normal plastic or stable phenotypes in cancer cells. Specifically, using data from experimentally evolved cancer cell lines, I will argue that normal pathways can be co-opted/expressed in atypical cellular contexts without the need for mutations or epigenetic modifications in genes associated with the typical expression of the phenotype itself. The co-option events can involve (i) microenvironmental stresses (for the plastic phenotypes) or (ii) independent nonspecific mutations (for stable phenotypes) that can elicit imbalances in the cell resulting in the activation of normal pathways through the fortuitous induction of the developmentally induced intracellular signal in a new/atypical context. Overall, the proposed scenarios bypass the need for specific parallel or convergent mutations for the evolution or expression of similar phenotypes. Such scenarios can switch the focus from searching for common genetic or epigenetic changes towards identifying the shared intracellular signals (e.g., changes in pH, redox status, levels of secondary messengers) associated with the independent expression of the same phenotype in both typical and atypical contexts.

Body size and sex differences affect cancer across species in lemurs

Erten E¹, Boddy A², Kokko H^{3,4}

¹Groningen Institute of Evolutionary Life Sciences, University Of Groningen, ²University of California Santa Barbara, ³Institute of Organismic and Molecular Evolution, University of Mainz, ⁴Institute for Quantitative and Computational Biosciences, University of Mainz

MEETING ROOM 122+123, August 22, 2025, 2:00 PM - 3:00 PM

Oncogenic mutations during cell divisions make organisms susceptible to cancer. Yet, although larger size typically requires more cell divisions, larger species are not more cancer-prone than smaller ones. Selection to suppress cancer until ages with low reproductive value can explain this pattern and predicts stronger cancer defences in larger species. Here, we test this by taking advantage of a high-resolution cancer dataset. We conceptualise cancer defences as the number and rate of mutations that result in cancer, which we estimate by fitting a multistage cancer model to age-specific cancer data with a maximum likelihood

approach. We build 10 models that differ in how defences relate to body size, species differences and sex differences, and select the best-performing ones with an information-theoretic approach. Our results suggest stronger cancer suppression in larger species, allowing them to evolve longer cancer-free lifespans. Moreover, we find a higher rate of oncogenesis in female lemurs than in males. Our study supports the hypothesis that selection matches cancer defences to species life history, explaining the lack of correlation between species size and cancer incidence.

Estimating excess cancer risk: an evolutionary approach

Nunney L¹

¹University Of California Riverside

MEETING ROOM 122+123, August 22, 2025, 2:00 PM - 3:00 PM

Background: For modern humans, the lifetime risk of many cancers has predictably increased with the rise in average lifespan; however, it has been noted that the prevalence of some cancers has risen disproportionately due to an additional increase in early-life incidence. It is important to know which cancers show this pattern so that we can begin to identify the causal factors. These cancers can be detected if their early-life increase has occurred over the modern period when recent epidemiological data can be compared to older data. A more general approach is to compare the current incidence of a cancer with the incidence expected in prehistoric times – which, of course, we do not know. However, we can use an evolutionary approach to estimate the maximum fitness loss expected before selection drives increased suppression of a given cancer. If the fitness loss that the current incidence pattern would have caused in a prehistoric human population is greater than the threshold value, then it is likely that some feature of modern human life has increased the incidence of that cancer.

Materials and methods: Prehistoric demography was estimated assuming that patterns of survival and fecundity were

similar to those estimated for hunter gather tribes, and varied according to the degree of parental care needed for offspring survival. These demographics were combined with worldwide incidence data for 70 different cancers in females and 66 in males to identify cancers whose modern incidence would have caused an excessive fitness loss in prehistoric times.

Results: It was found that approximately 10% of cancers caused an historical fitness loss above the estimated selection threshold. As expected, breast cancer in women was the disease causing the greatest potential fitness loss in a prehistoric population, while melanoma showed substantial geographical variation, with the highest fitness loss in Oceania (dominated by data from Australia); however, other results were less expected, such as the high potential fitness loss due to testicular cancer.

Conclusions: Those cancers with a high level of potential fitness loss are likely to have increased in frequency due to environmental or behavioural factors that have a greater influence on modern humans than on their ancestors. In some cases, the probable causes of the increase have been identified, but for others these urgently need to be identified.

Peristromal niches provide ecological rescue and facilitate the evolution of resistance to targeted therapies in lung cancer

Marusyk A¹

¹Moffitt Cancer Center

MEETING ROOM 122+123, August 22, 2025, 10:30 AM - 12:30 PM

Cancer therapies that target oncogenic signaling, such as inhibitors of ALK kinase (ALKi) in ALK mutant lung cancers, can induce strong and durable clinical responses. However, targeted therapies are not curative in advanced cancers as a subset of tumor cells typically survives, persisting within minimal residual disease, and eventually evolves resistance. While therapy resistance is typically attributed to cell-intrinsic (epi)mutational characteristics of tumor cells, it can also result from interactions of tumor cells with the tumor microenvironment (TME). In contrast to the detailed elucidation of the molecular mediators of therapy resistance, our knowledge of the evolutionary dynamics underlying the emergence of resistance remains poorly defined.

To dissect the relative contribution of cell-intrinsic and microenvironmental mediators of therapeutic resistance in vivo, we used mouse xenograft models of targetable lung cancers and histological analyses using tools adopted from spatial ecology. We found that therapy induced a profound shift in tumor cell proliferation towards peristromal niches, indicating an ecological rescue mechanism. Whereas this shift was most pronounced during remission, it was also partially retained during relapse, suggesting the direct contribution of peristromal niche to bona fide resistance (transition to net positive tumor growth). Mechanistically, partial protection of tumor cells within peristromal niches was

mediated by a combined effect of multiple juxtacrine and paracrine mechanisms that reduced drug sensitivity by activation of bypass signaling while also enhancing plasticity-mediated adaptation.

This protective effect of the peristromal niches was also a major modulator of the evolutionary dynamics of acquired resistance. Our in vivo cell competition experiments with spiked in resistant subpopulations revealed that the peristromal niche mediated an emergent positive ecological interaction between therapy-resistant and therapy-sensitive cells. By limiting tumor regression, the therapy-induced expansion of resistant cells limited the loss of protective peristromal niches, while the subsequent resumption of tumor growth created new peristromal niches capable of supporting the survival and proliferation of therapy-sensitive cells. The enhanced survival of therapy-sensitive cells potentiated their ability to adapt to therapies, potentiating the diversity of evolutionary trajectories towards resistance. Our results indicate that the acquisition of therapy resistance represents an eco-evolutionary process, thus requiring consideration of mechanistically complex cell-intrinsic and environmental effects. This complexity presents an inherent challenge to the success of current reductionistic approaches to cancer therapy, calling for the development of adaptive, evolutionary-informed therapeutic strategies.

Selection for function in cancer: a novel evolutionary principle with potentially groundbreaking therapeutic implications

Thomas F¹

¹CNRS

MEETING ROOM 122+123, August 22, 2025, 10:30 AM - 12:30 PM

Cancer is classically viewed as a disease driven by Darwinian selection acting at the cellular level, where fitter clones outcompete others within the tumor ecosystem. However, recent work suggests that this vision is incomplete. Tumor progression is not solely shaped by the survival of individual cells, but also by their capacity to organize into functional groups — a concept captured by the notion of Group Phenotypic Composition (GPC).

The ability of a tumor to develop, persist, and resist therapies critically depends on this GPC — i.e., the spatial and functional organization of its internal heterogeneity. Selection therefore acts not only on individual cell traits but also on emergent properties at the collective level:

cooperation, division of labor, resistance networks.

This new evolutionary framework — selection for function — opens original therapeutic avenues. Rather than only trying to kill cancer cells, future strategies could aim to destabilize the tumor's GPC, pushing the system beyond a tipping point, leading either to its collapse or to a trajectory shift towards a less aggressive state.

Such a perspective invites system-level therapies targeting not just cells but their interactions, key functional nodes, or microenvironmental dependencies. It also offers promising opportunities for adaptive therapies, capable of steering tumor evolution, controlling resistance, and potentially transforming cancer into a manageable chronic disease.

Selective sweep probabilities in tumours and other range expansions

Stein A², Kizhuttill R^{3,4}, Bak M¹, Bostock K¹, **Noble R¹**

¹City St George's, University of London, ²Queen Mary University of London, ³Indian Institute of Science Education and Research, Kolkata, ⁴University of California, San Diego

MEETING ROOM 122+123, August 22, 2025, 10:30 AM - 12:30 PM

Evolution during range expansions shapes biological systems from microbial communities and tumours up to invasive species. A fundamental question is whether, when a beneficial mutation arises during a range expansion, it will evade clonal interference and sweep through the population to fixation. However, most theoretical investigations of range expansions have been confined to regimes in which selective sweeps are effectively impossible, while studies of selective sweeps have either assumed constant population size or ignored spatial structure. I will present results of using mathematical modelling and analysis to investigate selective sweep probabilities in various biologically relevant scenarios, including the unexplored case in which mutants can outcompete and displace a slowly spreading wildtype. Assuming constant radial expansion speed, we derive probability

distributions for the arrival time and location of the first surviving mutant and hence find surprisingly simple approximate and exact expressions for selective sweep probabilities in one, two and three dimensions, which are independent of mutation rate. Using agent-based simulations, we show that our analytical results accurately predict selective sweep frequencies in the two-dimensional spatial Moran process, and that they remain informative even when mutation effects on fitness are random and multiplicative. We further compare and synthesize our results with those obtained for alternative growth laws. Parameterizing our model for human tumours, we find that selective sweeps are predicted to be rare except during very early solid tumour growth, thus providing a general, pan-cancer explanation for findings from recent sequencing studies.

Sublineage dynamics and mitochondrial DNA exchange in Tasmanian devils' transmissible cancers

Belkhir S¹, Murchison E¹

¹Department of Veterinary Medicine, University Of Cambridge

MEETING ROOM 122+123, August 22, 2025, 10:30 AM - 12:30 PM

Background: Transmissible cancers are a rare type of cancers in which the living tumour cells are physically transmitted between genetically unrelated individuals. In Tasmanian Devils, carnivorous marsupials endemic to the island of Tasmania, two transmissible cancers, named Devil Facial Tumour (DFT) 1 and 2, are found and have led to endangerment of the species. These cancer lineages emerged several decades ago, and have been clonally spreading since then, and they thus provide a good opportunity to study the long-term evolution of cancer cells, and their diversification into different lineages.

Materials and Methods:

Based on the most complete sample set ever considered to study these transmissible cancers, with data gathered from over 2500 tumours and their matched hosts collected in the field for the past 20 years, we investigated the genetic diversity of DFT1 and DFT2 in the wild. Using a cost-effective method for genotyping tumours based on low-coverage whole genome sequencing data, we analysed the spatial and temporal dynamics of subclones. Besides, we assessed the mitochondrial DNA (mtDNA) diversity and reconstructed maximum-likelihood phylogenies based on mtDNA variants.

Results: First, we confirmed the geographic structure of DFT1 and DFT2 at the clade level and documented the changes in the frequency and spatial repartition of clades across Tasmania over time. Looking at a finer scale approach, we revealed distinct

patterns of sublineage replacement in different populations of Tasmanian devils. These patterns seem to be linked with environmental factors and movements of spreader devils across Tasmania. We also revealed the potential for coinfection and highlight the strong force of infection of Devil Facial Tumour Disease. This is valuable data to understand and predict the spread and evolution of DFT1 and DFT2 in the field and inform conservation strategies for the species.

Additionally, phylogenies based on mtDNA were found to approximately recapitulate the genetic relationships expected based on nuclear DNA, except for discrepancies which revealed the occurrence of mtDNA horizontal transfers from transient hosts into the DFT1 tumour lineage. We investigated the genetic and geographic origins of the mtDNA haplotypes thereby incorporated into the tumours. We considered the evolutionary consequences that these exchanges could have for this transmissible cancer, and suspect that this type of horizontal transfers could be more frequent than we think, even in non-transmissible cancers.

Conclusion: Using methods from molecular evolution and phylogenetics, this work sheds light on some of the factors underlying the transmission and genome evolution of cancers turned into an infectious disease. It illustrates how transmissible cancers are a privileged model to study cancer in an evolutionary framework, as well as contributing to a better understanding of the Tasmanian Devils' disease and the management options.

The permissive binding theory of cancer: an evolutionary theory of metastasis

Weisman C¹

¹Princeton University

MEETING ROOM 122+123, August 22, 2025, 2:00 PM - 3:00 PM

The later stages of cancer, including the invasion and colonization of new tissues, remain especially mysterious compared to earlier stages like primary tumor formation. While we lack many details about both, we do have an apparently successful explanatory framework for the earlier stages: one in which genetic mutations hold ultimate causal and explanatory power. By contrast, on both empirical and conceptual grounds, it is not currently clear that mutations alone can explain the later stages of cancer. Can a different type of molecular change do better? Here, I will discuss the “permissive binding theory” of cancer, which proposes that novel protein binding interactions are the key causal and explanatory entity in invasion and metastasis. It posits that binding is more abundant at baseline than we observe because it is restricted in normal physiology; that any large perturbation to physiological state revives this baseline abundance, unleashing many new binding interactions; and that a subset of these cause the cellular functions at the heart of oncogenesis,

especially invasion and metastasis. Significant physiological perturbations occur in cancer cells in very early stages, and generally become more extreme with progression, providing interactions that continually fuel invasion and metastasis. The theory is compatible with, but not limited to, causal roles for the diverse molecular changes observed in cancer (e.g. gene expression or epigenetic changes), as these generally act causally upstream of proteins, and so may exert their effects by changing the protein binding interactions that occur in the cell. This admits the possibility that molecular changes that appear quite different may actually converge in creating the same few protein complexes, simplifying our picture of invasion and metastasis. If correct, the theory offers a concrete therapeutic strategy: targeting the key novel complexes. The theory is straightforwardly testable by large-scale identification of protein interactions in different cancers.

A New Strepsipteran Parasite *Xenos gadagkari* sp.nov and its effect on Microbial Communities of Primitively Eusocial wasp *Polistes wattii*

Nain D¹

¹Department Of Zoology, Panjab University, Chandigarh, ²Indian Institute of Science Education and Research, ³PG Department of Zoology, Sri Guru Gobind College

POSTER SESSION 1 - P01.114, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Strepsipteran insects are obligate endoparasites that infect a broad range of insect hosts, often inducing striking morphological, physiological, and behavioural modifications. Within this order, the genus *Xenos* has been notably associated with eusocial wasps. While the parasitic interaction between *Xenos vesparum* and *Polistes dominula* is well documented, such associations have remained unexplored in the Indian subcontinent until now. Our research documents the discovery of a novel strepsipteran species, *Xenos gadagkari*, parasitizing *Polistes wattii*, a widespread and ecologically significant wasp in North India. We provide a detailed morphometric description and establish the phylogenetic position of *X. gadagkari* within Strepsiptera. In addition to characterizing this new host-parasite relationship, we explored their

microbiological dimension. We employed 16S rRNA gene amplicon sequencing using Oxford Nanopore Technologies to compare the microbial communities of healthy and *Xenos*-parasitized male and female *P. wattii*. Our findings uncover the significantly higher bacterial diversity in parasitized individuals, confirming altered microbial colonization due to parasitism.

This study represents the first report of *Xenos* parasitism in Indian *Polistes* and the first microbiome analysis of this genus. Our findings underscore the intricate ecological and evolutionary implications of host-parasite-microbiome interactions and highlight the potential of *P. wattii* and *X. gadagkari* as a novel model system for studying coevolution and symbiotic dynamics in social insects.

Alternative photobiont - where did it come from? Metabarcoding exploration of algal diversity living on lichens in the phyllosphere framework.

Kosecka M¹, Ptach-Styn Ł¹, Jąkowski M²

¹Department of Plant Taxonomy and Nature Conservation, Faculty of Biology, University of Gdańsk, ²Center for Genomics and Applied Bioinformatics, Faculty of Biology, University of Gdańsk

POSTER SESSION 1 - **P01.094**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Lichens are iconic examples of symbiosis. Each thallus mainly comprises a fungus (heterotroph; mycobiont) and an algal and/or cyanobacterial partner (photoautotroph; photobiont). Lichens deposit extracellular polymeric substances (EPS) on the surface of their hyphae throughout the entire thallus, forming extracellular interaction matrices (EIM) that form the habitat for communities of algae, fungi, and bacteria. Furthermore, they form external and internal polysaccharide-dense zones depending on the structure of the lichen cortex. This feature allows the formation of intrathallic communities of algae, fungi, and bacteria (inside lichen thalli, under the cortex); and the formation of exolichenic biofilm (on the external part of the cortex) that includes the confirmed presence of bacteria and yeast, and probable presence of algal, and other filamentous fungal communities that in this area were not studied. Their existence was generally acknowledged but not verified; they were only considered contamination and removed.

However, we lack information on the extent to which the exolichenic biofilm constitutes a part of the lichen holobiome, and how it is structured in the framework of the surrounding environment – the phyllosphere and rhizosphere. From the studies on lichen photobionts, we know that under stress conditions, lichens exchange the intrathallic algal partner for a better-adapted one acquired from the surrounding different lichen species. However, we lack knowledge of the purpose of exolichenic biofilm, which may be a source of adapted algae. Therefore, we aim to evaluate community variation and interaction of the lichen algal components, including their position inside or on the surface of lichen thalli under varying air pollution levels.

Materials and methods: Fifteen young *Acer platanoides*, with three *Xanthotia parietina* thalli on the bark (45 specimens in total), were selected in five locations. The material was collected between

6 and 8 August. A procedure of sampling and sample processing, suitable for the study of their diversity by metabarcoding, was tested. Thirty-nine samples were collected from each tree, using mixed swab and whole thalli sampling methods, corresponding to specific algal communities: A. exolichenic; B. total community of lichen thalli; C. intrathallic; testing three surface sterilization methods; D. green algae from neighboring lichens; F. green algae inhabiting the dermosphere; G. green algae present in the phyllosphere. DNA isolation from 585 samples was performed using the Quick DNA Fecal/Soil Microbe Kit (ZymoResearch). To examine the diversity of selected algal communities, amplicons of the ITS2 rDNA region were prepared. Ligation of adapters necessary for sequencing and Illumina NovaSeq 2x250bp sequencing, was performed by an external company.

Results: PcoA analysis showed that it is impossible to distinguish completely the studied communities; they have a certain common part. Beta diversity and the Kruskal-Wallis test showed statistically significant differences between exolichenic and intrathallic communities. However, there were no significant differences between exolichenic communities and the dermosphere and phyllosphere, as well as the communities of green algae surrounding lichens. Analysis of the species composition of individual communities indicates that the same green algae species may occur in each community, but with varying abundance.

Conclusions: As the experiment did not allow for the description of unique exolichenic green algae communities, the hypothesis requires further verification. However, the obtained results may indicate that the method of exolichenic communities sampling using a swab may allow for the simultaneous assessment of the composition of the entire ecosystem.

POSTER SESSION 1 - P01.073, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Ancient genomic studies have extensively explored human-microbial interactions, yet research on non-human animals remains limited. Here, we analyzed ancient microbial DNA in 488 mammoth samples, of which 359 are newly sequenced, spanning a time transect from the Holocene to over a million years ago. After accounting for contamination and conducting phylogenetic analyses, we identified six bacterial clades related to modern commensal or putative pathogenic species. These include *Streptococcus* from woolly mammoth teeth

on Wrangel Island, *Erysipelothrix* from a 1.1-million-year-old steppe mammoth, and *Pasteurella*-related bacteria that have previously been linked to African elephant deaths. Although additional complete genomes are required to fully evaluate the gene content of the ancient mammoth bacteria, the identification of potential virulence genes suggests that some microbes could have played a pathogenic role. Collectively, these findings highlight the significance of ancient DNA in investigating the microbial ecosystems of extinct animals.

Can my gut save me? Heatwaves, cloacal microbiome and survival of lesser kestrel nestlings (*Falco naumanni*)

POSTER SESSION 1 - P01.113, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Microbial communities, particularly those in the gut, play key roles in host metabolism, development, and immune function, often being referred to as a “second genome.” Commensal microbiota can affect thermal tolerance and survival in laboratory studies, but evidence from wild populations is still limited. This knowledge gap is particularly pertinent in the context of climate change, where rising temperatures may disrupt host-microbiome interactions during critical life stages. In cavity-nesting birds like the lesser kestrel (*Falco naumanni*), nestlings are constrained to the microclimatic extreme conditions of the nest which has an immense impact on development and given so can impact their microbiome and long-term fitness.

Materials and Methods: We examined the impact of high temperatures during a heatwave on the cloacal microbiome of lesser kestrel nestlings by means of a nest cooling experiment that created a natural gradient of nest temperatures. Nest boxes placed on roof terraces were either shaded or left unshaded, resulting in an average nest temperature difference of ~4°C (range: 40.0–53.7 °C) during extreme heat events. This setup allowed us to assess how variation in microclimatic conditions affects the nestling microbiome. DNA was extracted from cloacal swabs, and the full-length 16S rRNA gene was amplified and sequenced using Oxford Nanopore's 16S Barcoding Kit 24 V14 (SQK-16S114.24). Sequences were processed and taxonomically assigned at the genus level using the EPI2ME 16S workflow (v1.4.0). The resulting genus-level abundance table was imported into R (v4.5.0) for diversity and statistical analyses to

evaluate associations between microbial diversity, nest temperature, and other ecological variables.

Results: Whereas preliminary analyses revealed no significant differences in overall microbiome community composition when comparing shaded and unshaded nest boxes directly, linear mixed models revealed that microbial diversity increased significantly with rising nest temperatures, regardless of shading treatment (Shannon index: $p = 0.021$; Simpson index: $p = 0.047$). Importantly, nestlings that died before fledging had significantly lower microbial diversity, as measured by both indices ($p < 0.05$), suggesting a potential link between reduced gut microbiome diversity and increased mortality risk. Across all samples, the dominant bacterial phyla were Proteobacteria (notably Pseudomonadota) and Firmicutes (Bacillota), consistent with patterns reported in other cavity-nesting bird species.

Conclusion: Our findings suggest that high nest temperatures during heatwaves can shape the gut microbiome diversity of lesser kestrel nestlings, with increased temperatures associated with higher microbial diversity. Critically, lower gut microbiome diversity can be linked to higher mortality risk before fledging, suggesting that microbiome health may play an important role in nestling survival under extreme climatic conditions. These findings underscore the role of microclimatic conditions and host-microbiome interactions in shaping fitness outcomes in wild bird populations, offering new perspectives on how climate variation may influence developmental and ecological processes.

Characterization of Microbial Communities in Winter Ticks & Moose in Maine

Miles M¹, Kantar L², Simpson B³, Ishaq S¹, Kamath P¹, De Urioste-Stone S¹

¹The University of Maine, ²Maine Department of Inland Fisheries and Wildlife, ³Penobscot Nation Department of Natural Resources

POSTER SESSION 1 - P01.115, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Winter ticks (*Dermacentor albipictus*) are ectoparasites that complete their entire one-year life cycle on a single host, preferentially the North American moose (*Alces alces*). Infestations can lead to significant health issues in moose, including anemia, hair loss, and death, especially in calves. Microbial communities within winter ticks may play roles in pathogen transmission to moose, raising concerns about ecological impacts beyond direct physical effects on moose health. While this study does not explicitly test evolutionary hypotheses, it provides foundational data relevant to understanding host-parasite-microbiome interactions, which are integral to evolutionary dynamics in host-parasite systems. The goal of this study is to (1) characterize microbial communities in winter ticks parasitizing moose in Maine and (2) identify potential shared pathogens between ticks and their hosts. In January 2024, winter ticks and paired whole blood samples (n=93, respectively) were collected from moose calves (~8 months old) and a few adults during live captures in Maine's MDIFW District 4 and Penobscot Nation Territory. DNA was extracted from all samples and the 16S rRNA region was amplified via PCR prior to sequencing at the University of New Hampshire's Hubbard Center for Genome Studies using an Illumina NovaSeq platform to characterize microbial communities. Data processing included cutadapt trimming, filtering, and taxonomic assignment using the DADA2 pipeline. Taxonomic assignment was conducted on moose samples using the SILVA v138.2 database, while winter tick data are currently undergoing taxonomy assignment. Contaminant sequences were identified and removed based on frequency and prevalence in negative controls. The quality of all samples was high, with 8,753 amplicon sequence variants (ASVs) identified in moose blood samples and 20,339 ASVs in winter tick samples. Moose samples had higher read retention (87%) compared to ticks

(57%), but tick samples retained more ASVs (91%) after chimera removal (compared to 81% in moose samples). The most abundant phyla in moose blood included Pseudomonadota, Bacillota, and Actinomycetota, with notable genera such as *Eperythrozoon*, *Pseudomonas*, and *Anaplasma*. Further analyses of winter tick microbiomes will provide insights into microbes that could potentially be vectored by these ticks in moose. This study offers a comprehensive metagenomic analysis of microbial communities in winter ticks and moose hosts. The microbial profiles found in moose blood are consistent with those of other mammals, consisting of diverse taxa from environmental and host-associated phyla. Despite lower read counts, winter ticks exhibited greater microbial diversity, with more ASVs detected than in moose samples. Ongoing analyses will focus on refining data, standardizing species richness using rarefaction, and conducting statistical comparisons of alpha and beta diversity to explore differences in microbial structure. Comparative taxonomic analysis will also assess microbial overlap and identify potential shared pathogens between moose and winter ticks. These efforts will illuminate the functional roles of these microbial communities and their potential implications for moose health. A deeper understanding of the complex interactions among moose, ticks, and their associated microbes is essential for informing future wildlife disease management strategies. The findings of this research have the potential to significantly impact wildlife management, particularly in areas that may be affected by future climate change. Understanding how shifts in temperature and habitat could alter tick populations and pathogen transmission is crucial for predicting future health threats to moose and other wildlife. This study has the potential to enhance our knowledge of tick-borne diseases and could aid future mitigation strategies.

Comparative microbiome analyses reveal differences between wild and captive populations of the Montseny Brook Newt (*Calotriton arnoldi*)

POSTER SESSION 1 - **P01.078**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The Montseny brook newt, *Calotriton arnoldi*, is a Critically Endangered amphibian species endemic to the Montseny Massif in Catalonia, Northeastern Spain. Due to population declines and threats to its natural habitat, an ex-situ breeding program was initiated in 2007. A key goal of the program is to ensure the survival of captive-bred individuals after reintroduction, which in amphibians heavily relies on the specimens' microbiome being capable of protecting them from environmental microorganisms, especially considering the global Chytridiomycosis pandemic caused by the fungi *Batrachochytrium dendrobatidis* (Bd) and *Batrachochytrium salamandrivorans* (Bsal). This study aims to characterize the microbiome of wild and captive specimens of *Calotriton arnoldi*, to identify differences in microbiome composition, and to determine their potential impact on captive-bred individuals upon reintroduction. Up to 7,438 ASVs (Amplicon Sequence Variants)

were identified from 138 samples from 21 and 61 wild and captive-bred individuals, respectively. Results indicate that wild populations from different subspecies have significantly different microbiome composition, as do wild and captive-bred groups from the same subspecies.

Additionally, dissimilarities in microbiome variability were only found within each subspecies, between wild and captive-bred groups. In terms of composition, certain bacteria were identified as potential markers for both wild and captive environments. Enhancing microbiome variability might improve the survival prospects of reintroduced specimens. Thus, subjecting captive specimens to a more natural environment while in captivity or a soft-release procedure could potentially mitigate the absence of exposure to other bacteria and potential pathogens from their native environment.

Development and Stability of the Equine Gut Microbiome: Microbial Succession in Foals and Seasonal Variation in Adult Horses at the Spanish Riding School

Sevatdal S¹, Sæbø M¹, Sommerauer S², Sønstebo J¹

¹University Of South-eastern Norway, ²The Spanish Riding School

POSTER SESSION 1 - **P01.108**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The equine gut microbiome plays a central role in digestion, immune function, and overall well-being. Microbial fermentation in the hindgut enables the breakdown of fibrous plant material, producing vital nutrients and energy. Early in life, foals acquire their microbiota through maternal transfer and dietary changes that shape long-term microbial development. In adult horses, factors such as feeding routines, physical activity, and seasonal variations can also influence gut microbial composition. Understanding these microbial dynamics is essential to support the health and performance of horses of all ages and breeds.

Materials and Methods: This study combines two research efforts, both conducted on Lipizzaner horses at the Spanish Riding School in Vienna:

1. **Foal development study:** We followed 15 mare–foal pairs from birth to 12 weeks of age. Fecal samples were collected at several time points to monitor the development of the gut microbiota as the foals transition from milk to forage.
2. **Adult horse study:** In parallel, we are studying 20 adult stallions over a 12-month period to characterize their core gut microbiome and investigate how it responds to seasonal changes, dietary changes, training intensity and general health.

Microbial DNA was extracted from fecal samples, and the V4 region of the 16S rRNA gene was amplified and sequenced using Illumina technology. The data is analyzed to assess microbial diversity, community composition, and key factors influencing variation over time.

Results:

Initial sequencing and data processing have provided an overview of the microbial communities present in both foals and adult horses. Preliminary observations suggest dynamic shifts in gut microbiota during the early postnatal period, likely reflecting the influence of maternal microbiota and dietary changes. In adult horses, variation in microbial composition appears to correspond with temporal and environmental factors across the sampling period. Ongoing analyses aim to further characterize microbial patterns and identify potential core taxa shared across individuals and time points.

Conclusions: The findings from this study may guide future research and management strategies aimed at promoting a stable and resilient gut microbiome, supporting equine health and well-being from early development through adulthood.

Diet-microbiome associations in a wild Swedish carnivore

Enkvist C¹, Videvall E¹

¹Uppsala university

POSTER SESSION 1 - P01.080, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The bacterial assembly of the gastrointestinal tracts in animals, i.e. the gut microbiota, provides the host with essential functions. Gut microbiota have been known to mediate host metabolism, train the immune system, digest food, and synthesize vitamins, yet it is still poorly studied in wild carnivore species. The wolverine (*Gulo gulo*) is an important Palearctic mustelid carnivore and scavenger, known for feeding on ungulate carcasses, hunting reindeer calves and food-stashing behavior. The Swedish population is considered vulnerable due to historic population declines and current low genetic diversity. Despite the wolverine's important ecological role and unique feeding behavior, its gut microbiota has never been studied in detail. Using a set of fecal samples collected for a national population survey, spanning the entire Swedish population, we sequenced the bacterial 16S rRNA gene in

over 400 wild individuals. The first aim is to characterize the wolverine gut microbiome composition, both spatially and temporally. We also plan to sequence the mitochondrial 12S rRNA gene of the same samples to characterize the host diet composition and perform diet-microbiome association analyses. Furthermore, to investigate how captivity impacts the gut microbiota of wolverines, we are sequencing samples from captive wolverines across fourteen European zoos. This large data set, comprising both diet and microbiome data from wild and captive individuals, will provide unique insights into geographical and environmental differences by taking advantage of existing samples collected for monitoring purposes. This research will be important to further our limited knowledge on wild and captive carnivore microbiota and diet to better protect the wolverine.

Diet-microbiome covariation across three giraffe species in a close-contact zone

¹Uppsala University, ²Brown University, ³Giraffe Conservation Foundation, ⁴Mpala Research Centre, ⁵East African Herbarium

POSTER SESSION 1 - P01.104, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The biodiverse group of ruminant mammals are entirely dependent on their gut microbiota to extract energy and nutrients from their foods, making these symbionts vital to survival. Because variation in wildlife diets can select for distinct communities of gut bacteria, different foraging choices can have both nutritional effects and other microbially-mediated effects on animal well-being. Despite the proliferation of studies focusing on host-microbiome interactions in recent decades, few prior studies have quantified the level and extent of diet-microbiome linkages in wildlife. Therefore, we used DNA metabarcoding to compare the diets and gut microbiomes of giraffes, the world's largest ruminant. We focused on three giraffe species—reticulated, northern, and Masai—that occur along a near-contact zone in equatorial Kenya. We found large differences in both the composition and diversity of diets and microbiomes within and among populations. However, contrary to expectations, we found very little evidence

for links between the composition of individual diets and their corresponding microbiomes. Instead, geographic proximity strongly predicted diet similarity whereas host-species identity strongly predicted microbiome composition. The lack of diet-microbiome linkages across these giraffe populations—coupled with the evidence that species differed strongly in diet and microbiome compositions—highlights the possibility that their history of ecological and evolutionary divergence has generated unique, species-specific gut microbiomes. Moreover, striking levels of diet variation were revealed among neighboring populations of giraffe from the same species, and thus baseline knowledge of their resource-use diversity could support ongoing efforts to geographically tailor management strategies aimed at conserving local food staples under environmental change.

Different drivers govern the fungi and bacteria components in the dung beetle microbiota

Natta G¹, **Roggero A¹**, Voyron S^{1,2}, Lumini E^{1,2}, Fiorito A¹, Laini A¹, Rolando A¹, Palestini C¹

¹Department of Life Science and Systems Biology, ²Institute for Sustainable Plant Protection National Research Council

POSTER SESSION 1 - **P01.077**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Many of the ecological services associated with coprophagy are provided by symbiotic microorganisms, namely the gut microbiota, the action of which may depend on host behaviour and ecology. The gut microbiota also influences dung beetle growth and development. The taxonomic composition of the gut microbiota is affected by various factors; of these, phylogeny plays a greater role than habitat or diet. The switching of the microbiota between syntopic sister species (e.g., *O. vacca/medius* and *O. taurus/illyricus*) causes significant problems. Intraspecific microbial variability is also very high due to vertical parental derivation. In *Onthophagus* the transmission of maternal microbiota occurs through the pedestal—a fecal secretion emitted by the female, on which she lays her eggs and the larvae feed after hatching. The present research examined the gut prokaryotes and fungi of wild adults collected from different types of dung located in distinct pastures. Our aim was to understand whether species identity affects the microbiota more than dung type and whether this conditioning applies equally to prokaryotes and fungi.

Materials and methods: Individuals of *Onthophagus fracticornis*, *O. medius* and *O. verticicornis* were collected from the western Alps (45.136° N, 7.296° E) from different types of dung (cow, sheep and donkey) located in distinct pastures. Following species confirmation by COI barcoding (in BOLD and ASAP), we selected 30 adults (15 males/15 females) of each species per dung type. After a 24h fast, the entire gut of each individual was dissected out and the prokaryotic (archaea and bacteria) and fungal components of the gut microbiota identified using the 16S ribosomal RNA (rRNA) gene and nuclear ribosomal ITS2 region, respectively. Statistical analyses were conducted for prokaryotes and

fungi separately, visualizing inter-species and inter-individual dissimilarities by means of non-metric multidimensional scaling (nMDS). Envfit analysis on the nMDS ordination determined which factor differentiated individuals the most.

Results: The relationships among the *Onthophagus* (*Paleonthophagus*) species were confirmed by phylogenetic analysis. The ordination plot of prokaryotes showed a clearer separation of points in the nMDS space, with individuals grouped by species rather than dung type. In the envfit analysis, species R² = 35.7% (p = 0.001). Dung type and sex accounted for 15 (p = 0.001) and 10.1% (p = 0.001), respectively. Conversely, the fungi ordination plot showed a clearer distribution of the points in the nMDS space, with individuals grouped by dung type rather than species. The R² value for dung type was highest (R² = 30.4%; p = 0.001), whereas species and sex accounted for 5.2 (p = 0.051) and 1.3 % (p = 0.282), respectively.

Conclusions: Microbial variation depends on phylogeny and diet. We found the gut microbiota composition to reflect two divergent trends: i) the prokaryotic component varied according to host species, with distinctions in even phylogenetically very close species, whereas it was constant within each species regardless of the dung type; ii) by contrast, the fungal component derived, at least in part, from the host's diet, being relatively constant within each dung type regardless of the species. Most prokaryotes of dung beetle microbiota were definitive symbionts, whereas many fungi were transient symbionts. These results support the notion that certain lineages of bacteria beneficial for host nutrition may be transmitted from mother to offspring, creating a kind of species-specific microbiota.

Early life assembly of the gut microbiome and its consequences in wild Soay sheep

Sweeny A¹, Lemon H², Bal X¹, Free A¹, Childs D³, Nussey D¹, McNally L¹

¹University of Edinburgh, ²University of Oxford, ³University of Sheffield

POSTER SESSION 1 - P01.112, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The gut microbiome (GM) exerts profound influences on host biology, shaping digestion, immune function, and pathogen defense. Early life represents a critical window for GM assembly, with long-lasting effects on host development. Because much of our existing knowledge regarding GM development comes from model systems, primates, and humans, more insight is needed into patterns of GM assembly across a diverse range of hosts. To address this gap, we investigated GM development across the first year of life in wild Soay sheep (*Ovis aries*), a natural population living on the island of Hirta in the St Kilda archipelago.

We sampled over 250 individuals longitudinally across five timepoints, generating >1000 samples spanning neonates (<1 month), lambs (2–12 months), and adults (>1 year). We observed striking differences in alpha and beta diversity, as well as microbial life history traits, across age classes. Neonatal communities were exceptionally low in diversity and highly dynamic, with composition shifting markedly during the first few months but remaining distinct from adults until 12 months of age.

Juvenile GM profiles featured high relative abundances of putative pathobionts, which declined as the microbiome stabilised. In contrast, taxa associated with fibre degradation and ruminal development increased significantly post-weaning, mirroring a dietary transition from milk to forage.

Lamb GMs also exhibited rapid microbial growth rates and enrichment of opportunistic taxa capable of exploiting naïve, nutrient-rich environments. Intriguingly, individuals with the fastest GM growth showed reduced overwinter survival, suggesting that these opportunistic taxa may out-compete other beneficial core GM taxa. Additionally, we detected higher microbiota similarity between lambs and their mothers compared to lambs and random ewes, indicating some maternal contribution to GM assembly. I will present dynamics of early-life GM development in wild Soay sheep, explore how these patterns intersect with host health and survival, and discuss the broader implications for understanding how GM assembly in early life may shape long-term outcomes in natural populations.

Egg and embryo microbiomes in the house sparrow (*Passer domesticus*): acquisition and consequences for embryo success

Wolfe S¹, Risse J², Pijl A², Trevelline B^{1,3}, Rowe M²

¹Cornell Lab of Ornithology, Cornell University, ²Department of Animal Ecology, Netherlands Institute of Ecology (NIOO-KNAW), 6700 AB, ³Department of Biological Sciences, Kent State University

POSTER SESSION 1 - P01.102, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

All animals host microbial communities in and on their bodies, and recent studies have shown that variation in these microbiomes can have major effects on host phenotypes. Most notably, the vertebrate gut microbiome mediates critical host physiological processes, including digestion, development, immunity, and behaviour. How these gut microbes are initially acquired, however, is unclear. In oviparous vertebrates, some studies suggest that embryos develop in a sterile environment and gut microbiota are acquired after hatching. However, recent studies have begun to challenge this hypothesis, suggesting instead that gut microbes may be acquired in ovo, either via maternal transmission before laying or via trans-shell penetration of nest microbes. As such, our understanding of how oviparous vertebrates acquire their gut microbiome remains a topic of debate. Furthermore, whether the putative embryonic gut microbiome contribute to embryo success is unknown.

We used 16S rRNA sequencing and bacterial culturing to investigate the egg and embryo microbiomes of house sparrows (*Passer domesticus*). Specifically, we investigated the bacterial communities of eggs (yolk and albumen) immediately after lay, as well as embryos (yolk, albumen, and gut) that were

incubated either naturally in the nest or artificially under sterile conditions. We also sequenced the bacterial communities of the nest environment and female cloaca. Combined, these data allowed us to determine whether living bacteria colonise eggs or embryos prior to hatching, and explore the likely mechanisms of early-life microbiome acquisition. We also scored embryo survival and measured embryo body mass to investigate potential correlations between microbiota and embryo fitness proxies.

We successfully sequenced and cultured bacteria from eggs and embryos, which supports the existence of a living egg microbiome. Intriguingly, our data suggest that the nest environment has a relatively minor contribution to the microbiome of pre-hatch embryos. We also observed significant shifts in the yolk and albumen microbiomes between lay day eggs and embryos, even when eggs were incubated under sterile conditions. This finding suggests that the egg microbiome undergoes microbial succession during incubation. Taken together, our findings highlight the dynamic nature of the egg microbiome and suggest that bird microbiomes may accompany their hosts throughout their entire life cycles.

Ethanol preference as adaptive plasticity? Behavioral and microbiotic shifts in *Nosema*-infected honeybees

Ostap-Chęć M¹, Antot W¹, Stec D¹, Miler K¹

¹Institute of Systematics and Evolution of Animals, Polish Academy of Sciences

POSTER SESSION 1 - P01.082, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Microbial communities within the gut play a central role in host physiology, influencing digestion, immunity, and behavior. In honeybees (*Apis mellifera*), the microsporidian parasite *Nosema ceranae* is a widespread, chronic, and often sublethal member of the gut microbiota. While typically framed as an invading pathogen, *Nosema* also functions as a background parasitic symbiont, routinely present at low abundance, that interacts with other gut microbes and host traits. It disrupts midgut function, leading to energetic stress and premature mortality, only under high infection levels. Here, we investigate whether *Nosema*-driven stress triggers behavioral plasticity in dietary preferences and whether such responses mitigate the costs of infection. We also assess how infection influences gut microbial composition, potentially contributing to broader microbiota-mediated host adaptation.

Materials and methods: We combined a meta-analysis of food intake in *Nosema*-infected vs. control bees with three additional laboratory experiments using caged bees of known age. In our experiments, individuals were assigned to control or infected groups, the latter receiving 100,000 *N. ceranae* spores in sucrose solution and the former receiving pure sucrose. Mortality was tracked for two weeks. In the meta-analysis and one experiment, we studied sucrose intake to test for compensatory feeding. In another experiment, bees were offered a choice between plain sucrose and ethanol-spiked solutions (0.5% or 1%) to assess infection-induced shifts in preference. In the third experiment, gut microbial communities were characterized by 16S rRNA gene metabarcoding (V3–V4 region), with analyses of alpha/beta diversity and differential abundance of sequence variants. Spore loads were quantified using qPCR to

confirm infection status and group differentiation.

Results: qPCR confirmed that infected bees had significantly higher spore loads than controls, validating the treatment groups in all experiments. Infection did not lead to increased total sucrose intake, suggesting no compensatory feeding response. However, infected bees showed a significantly higher preference for ethanol-spiked solutions, indicating an infection-linked behavioral shift. Moreover, while access to 1% ethanol reduced survival in control bees, this effect was less pronounced in infected bees, pointing to a potential buffering effect of ethanol under infection stress. Nevertheless, access to ethanol did not reduce parasite load. Gut microbiota composition did not differ strongly between groups, but several sequence variants varied in abundance, reflecting subtle changes of the microbial community in response to the developed infection.

Conclusions: Our results suggest that *Nosema* infection can trigger adaptive host plasticity via altered dietary behavior. This response, specifically the increased ethanol preference, may help bees mitigate the energetic and physiological costs of infection, even without stopping the proliferation of the parasite. Rather than dramatically reshaping the microbiota community, infection coincides with subtle shifts in microbial composition, indicating the complex interplay between pathogenic and other microbes in shaping host resilience. Our findings support the view that members of the gut community play a role in behavioral and physiological plasticity in hosts, even in the context of parasitism. More broadly, this work highlights how parasitic infections, as part of the microbial landscape, can shape context-dependent host adaptations.

Exploring the Effects of Habitat Modification on Rodent Gut Microbial Communities in the Yucatán Peninsula

Borja-martínez G¹, Vázquez-Domínguez E¹, Epps C¹

¹Institute of Ecology

POSTER SESSION 1 - P01.087, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Habitat modification in natural forests is associated with changes in land use and resource availability, resulting in complex landscapes consisting of a heterogeneous mosaic of old-growth and secondary forest patches surrounded by different types of anthropogenic land cover (e.g., crops, cattle pastures, urban areas, roads). Wildlife tends to modify its behavior, diet, and dispersal patterns in response to such habitat modification. Environmental modifications also shape the assembly of microbial communities, their taxonomic, genetic, and functional diversity, altering the host-microbiome evolutionary relationships. The unevenness in animal microbial communities, known as dysbiosis, is related among others to changes in diet, pollution, urbanization, agriculture and grazing activities. Our objective was to determine the effects of habitat modification on the assembly of gut microbial communities in wild rodent species across landscapes with different modification levels, using an innovative network approach in a multiple host species system.

Materials and Methods: Our study encompasses three geographic regions in the Yucatán peninsula, Mexico, each representing different degrees of habitat modification: urban (Mérida), rural (Tizimín), and natural (Calakmul); within each region, we selected three sites representing a local habitat gradient from urbanized to conserved. To characterize regions and sites, we estimated the cover percentage of crops, urban areas, and bare soil using Sentinel images. We sampled the rodent community in each region and sequenced the 16S rRNA V4 gene in 67 rodent individuals of six rodent species. We estimated different indices, including alpha diversity within regions, beta diversity and dispersion, and evaluated differences among sites. We built co-occurrence networks per site and estimated the number of nodes, edges, and modules, and vulnerability. We associated these metrics with the landscape variables using linear

models and determined the microbial identity within each module.

Results: Microbial richness increased with habitat modification in the three regions, while the number of common species was higher in rural habitats. We identified significant bacterial structure between natural and urban sites in Tizimín and between natural and rural sites in Mérida. Regarding the landscape variables, we found that the abundance of microbial taxa was shaped mainly by bare soils. When comparing the global networks, results showed that Tizimín had a greater number of edges and nodes, while Mérida had the lowest; connectivity in Mérida lacked keystone taxa. Comparatively, network patterns per site showed that rural sites had more edges and nodes, while the number of modules increased with habitat modification gradient. These network properties were mainly associated with bare soils and crops. Furthermore, several bacterial families in different modules were associated with urban cover in Mérida and Tizimín rural sites.

Conclusions: Our findings show a common response to habitat modification across regions. Urban gut microbiota exhibits higher richness but greater homogeneity, which can have negative or positive consequences for fitness, depending on the particular microbes' function. Rural microbiota has a greater number of correlated taxa forming networks, likely due to the heterogeneous land cover types in these habitats. Additionally, habitat modification increases the number of modules or functional units of the microbial networks, while decreasing their connectivity and complexity. This indicates a strong functional selection or the random colonization of new species (dysbiosis), while simultaneously restricting the type of organisms that can colonize the host, leading to homogenization. Overall, microbiome network structure and composition are associated with urban surfaces and bare soils.

Exploring the role of *Zostera marina*'s microbiome composition under heat stress across life stages and populations

Bakowski C¹, Willim J, Reusch T

¹Marine Evolutionary Ecology, GEOMAR Helmholtz Centre for Ocean Research Kiel

POSTER SESSION 1 - **P01.096**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Seagrasses are the only flowering plants to have successfully adapted to marine environments. Approximately 70 species are distributed across all the continents' coasts, except Antarctica, providing a wide range of ecosystem services, including coastal protection, carbon sequestration, and habitat provisioning for diverse marine life. Despite their ecological importance, seagrasses face mounting threats from climate change, especially rising temperatures and nutrient pollution. While the effects of abiotic stressors on seagrass health have been the focus of many studies, the role of biotic interactions -- particularly those involving associated microbial communities -- and the interplay between biotic and abiotic stressors remain poorly understood. In particular, the composition and functional significance of the seagrass microbiome in response to environmental stressors are still largely unexplored.

We hypothesize that the composition and function of the seagrass microbiome contribute to host stress tolerance and local adaptation, as demonstrated in terrestrial plants. We expect the local microbial communities to play a particularly significant role in enhancing stress resilience during early life stages of seagrass.

Our model species is *Zostera marina*, one of the most extensively studied and widely distributed seagrass species, which thrives across a broad range of environmental gradients, including differing depths, salinities, and temperatures. In an acute heat stress experiment simulating summer heat waves, *Z. marina* plants from different Baltic Sea populations and three different life stages (6-month-old juveniles, 18-month-old-juveniles and fully-grown adults) were

examined. Both juvenile groups exhibited lower mortality while the youngest plants even showed a higher photosynthetic efficiency under heat stress, suggesting a more flexible and resilient metabolism compared to the fully-grown adults.

To investigate these dynamics, we extracted microbial DNA from plant parts of the different groups of the experiment, as well from the roots, the surrounding sediment, and ambient water. Amplicon sequencing was performed using a targeted set of 16S, 18S, and ITS primers to characterize key prokaryotic and eukaryotic microbial groups associated with *Z. marina*. A particular focus in the composition analyses is placed on diverse eukaryotic endophyte, including *Phytophthora* spp. and *Labyrinthula* spp., a group of protists consistently associated with *Z. marina*. Under stressful conditions, *Labyrinthula* spp. is hypothesized to become pathogenic, causing the so-called wasting disease -- a phenomenon responsible for a dramatic decline (~90%) of *Z. marina* populations along the Atlantic coast in the 1930s. Despite decades of research, the host-pathogen dynamics of this and other eukaryote-plant interactions remain poorly understood.

As climate change continues to intensify abiotic challenges for aquatic plants, understanding the complex interactions between seagrasses and their microbiomes is essential for predicting their resilience and informing conservation strategies. Insights from this study provide a deeper understanding of how microbial communities contribute to the persistence and possible evolutionary rescue of *Z. marina* under increasing environmental stress.

Facultative symbionts and climatic adaptation: testing thermal benefits of *Hamiltonella defensa* in aphids across latitudes

Stalder D^{1,2}, Wallisch J¹, Hudson C¹, Vorburger C^{1,2}

¹Department of Aquatic Ecology, EAWAG, Swiss Federal Institute of Aquatic Science and Technology, ²D-USYS, Department of Environmental Systems Science, ETH Zürich

POSTER SESSION 1 - P01.090, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Host-associated microbes can modify ecologically relevant traits and thus shape the evolution of their hosts. In aphids, facultative endosymbiotic bacteria may impose costs, such as a reduced lifespan, but can also provide a range of benefits, including protection from natural enemies and increased tolerance of heat stress.

The heritable endosymbiont *Hamiltonella defensa* is best known for rendering its aphid hosts resistant to parasitoid wasps. However, it has also been linked to enhanced thermal tolerance of its host. This effect might be relevant to explain seasonal as well as spatial associations between symbiont prevalence and temperature. In the black bean aphid (*Aphis fabae*), there is a striking pattern of decreasing *H. defensa* prevalence with increasing latitude. The southern range also harbors greater strain diversity in this symbiont. This raises the possibility that *H. defensa* may contribute to temperature adaptation in aphids.

To test this hypothesis, we compared the performance of multiple *A. fabae* lines, both infected and uninfected with *H. defensa*, originating from temperate (Germany) and Mediterranean (southern Italy) regions under cold (13 °C), intermediate (20 °C), and hot

(27 °C) conditions. Using a combination of antibiotic curing and artificial infection, we leveraged the clonal reproduction of aphids to separate the symbiont's effects from those of the host genotype. This allowed us to quantify the relative contributions of host and symbiont genotype to reproductive fitness across different temperatures.

The symbiont's effect varied among strains, across temperature, and also depended on the host genetic background, resulting in significant G×G×E interactions. Host genotypes showed the strongest and most predictable patterns of fitness across temperatures. Interestingly, aphid genotypes collected in southern Europe tended to perform better at the lowest temperature, which may be related to life-cycle differences. While northern populations overwinter as frost-resistant eggs, southern populations more often overwinter as adults, albeit at rather cool temperatures.

Overall, our findings suggest that the latitudinal distribution of *H. defensa* in *A. fabae* is unlikely to be driven by direct thermal benefits, pointing to a limited role of this symbiont in climate adaptation of aphids.

Fast-paced evolution of commensal bacteria facilitates insect host development under chemical stress

Henry Y¹, Gonzalez J¹, Posse A¹, Kawecki T¹

¹UNIL

POSTER SESSION 1 - **P01.079**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Human-made alterations to the environment are threatening insect biodiversity at an unprecedented rate. Anthropogenic chemicals such as insecticides and antibiotics are especially dangerous, as they can be released suddenly and in large quantities, leaving insects little time to adapt. Yet, insects may not be entirely defenseless. It has been proposed –but never experimentally confirmed– that the microbiome, i.e. the microbial communities associated with a host, could enable fast adaptation in response to stress. Using an experimental evolution experiment, we explored how environments polluted with an insecticide (imidacloprid) or an antibiotic (triclosan) could drive the evolution of *Gluconobacter oxydans*, a species naive to these chemicals and to *Drosophila*. With this setup, we also tested if these bacteria could associate with *Drosophila* larvae, and whether this association influenced their evolutionary trajectories compared to

bacteria evolved independently. After 10 fly generations of evolution (approx. 300 generations for bacteria), we observed faster development in bacteria-associated larvae, beyond that provided by bacteria at generation 0. This improvement was independent of larval presence, indicating bacterial adaptation to the fly food resource itself. Insecticide- or antibiotic-contaminated food caused developmental delays in larvae, but bacteria evolved on these chemicals fully rescued larval development in a compound-specific way. Consistent with this, we identified genetic changes in *G. oxydans* associated with the chemical they evolved with, highlighting potential targets for adaptation. Altogether, these findings suggest that the microbiome may indeed offer a mechanism for rapid host adaptation, although in *Drosophila* this appears to rely more on bacterial adaptation to environmental resources than on indirect effects involving the host.

Field realistic stressors alter the bee gut microbiome

Diaz M¹, Fruciano C², Botias C³, O'Connell D¹, Marshall K¹, Hildebrand F⁴, Brereton N¹, Goulson D⁵, Hughes W⁵, **Jones J**¹

¹University College Dublin, ²Institute for Marine Biological Resources and Biotechnology (CNR-IRBIM),

³Department of Life Sciences, University of Alcala, ⁴Gut Microbes and Health, Quadram Institute

Bioscience, ⁵School of Life Sciences, Department of Evolution, Behaviour and Environment, University of Sussex

POSTER SESSION 1 - P01.099, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Gut bacterial communities are known to regulate a variety of important functions in their animal hosts, including in the key pollinators bumblebees and honey bees. In bumblebees, the specialised gut microbiome ubiquitous across *Bombus* species is thought to contribute to host digestion, behaviour, and pathogen defence. Similar to honey bees, bumblebees have a simple but distinctive gut bacterial community. However, the interactions and potential sensitivity of these important gut microbiome functions to environmental stressors remains undetermined. We used controlled laboratory analyses to investigate which combinations of field realistic stressors may be influencing bee gut microbial communities. We exposed 40 bumblebee colonies, *Bombus terrestris*, to combinations of a pathogen, fungicide and pesticide commonly found in agricultural land, and assessed the gut bacterial communities of the bees using amplicon

sequencing. We show that some non-core taxa of the *Bombus* gut microbiome from the family Burkholderiaceae significantly differed in relative abundances in bees exposed to the field-realistic stressors when compared to controls. These findings highlight that some non-core gut microbiome taxa may be contributing to bumblebee adaptation to agricultural land, and are therefore important targets for functional analyses. In a key next step we have recently completed shot-gun sequencing of a unique set of 150 honey bee colonies from across the island of Ireland where pesticide and pathogen exposure has already been analysed for the same colonies. Both datasets are driving forward our understanding of bee host-gut microbiome interactions and the role of the gut microbiome in the evolutionary process, important for supporting pollinator resilience in the face of global change.

Genotype–environment interactions determine microbiota symbiosis in Syllidae polychaetes

Álvarez-Campos P¹, Riesgo A², Díez-Vives C²

¹Universidad Autónoma de Madrid, ²Museo Nacional de Ciencias Naturales de Madrid, CSIC

POSTER SESSION 1 - **P01.103**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

While most animals possess species-specific microbiomes, the microbial symbionts associated with Syllidae polychaete annelids remain largely uncharacterized, despite their ecological significance as one of the main components of the oceanic benthos. In addition, the genetic and environmental factors that influence the structuring of microbial communities at the intraspecific level have been never studied in this family.

Thus, in order to dig into the host-specificity patterns of Syllidae species, we have analyzed the microbiome of different species collected in the Mediterranean Sea, Pacific and Atlantic Oceans, by amplicon sequencing of the microbial 16S rRNA gene. Furthermore, we have examined whether

geographic location or genetic structure of conspecific syllids mainly collected in the Canary Islands, influences their microbial assembly. As it was previously found in other marine invertebrates, host specificity at the genotypic level was observed in syllid species characterized by highly isolated populations (i.e., limited gene flow). In contrast, in species exhibiting high gene flow, microbial community composition appeared to be shaped more by geographic location than by host genetic divergence. Our findings indicate that, in syllid species exhibiting high population structure, host genetic clustering exerts a greater influence on microbial community composition than geographic location.

Gut Microbial Dynamics in Atlantic Salmon: A Natural Field-Based Common Garden Experiment on the Role of Host, Environment, and Stochastic Processes

Schaal P², Cheaib B, Kaufmann J, Phillips K, Waters C, Ryder L, Llewellyn M², McGinnity P, **Heys C**^{1,2}

¹University Of Lancashire, ²University of Glasgow

POSTER SESSION 1 - **P01.070**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Intestinal microbial communities are shaped by various ecological factors, including both environmental (E) and host-specific (G) influences (G×E). Few studies have assessed how these factors shape gut microbiota in Atlantic salmon populations in the wild. Here, we examine the roles of biotic, abiotic, and stochastic factors in shaping the gut microbiota of juvenile farmed, wild, and hybrid Atlantic salmon (*Salmo salar*) in a natural river system. Distinct microbial communities were found in the water, gut, and macroinvertebrates, with source tracking suggesting that most taxa in the salmon intestine originated from macroinvertebrates, a primary food source, rather than the water column. Seasonal shifts were observed in the contribution of macroinvertebrates to the gut microbiota, with the lowest contribution in winter and increased contributions in March and May, reflecting changes in food availability and fish appetite. Neutral modelling revealed that 86% of gut taxa were transient,

underscoring the dynamic nature of the gut microbiome. Additionally, host genetic background influenced microbial composition, with distinct assemblages observed between farmed and wild salmon. Our study highlights the complex interplay of deterministic and stochastic processes in shaping the gut microbiome of juvenile Atlantic salmon. The consumption of macroinvertebrates was identified as an important driver of microbial community composition, with seasonality influencing gut diversity. The high proportion of transient taxa emphasizes the need to distinguish between resident and transient microbes, especially in dynamic natural environments. Furthermore, the host's genetic background contributes to microbial variation, adding another layer of complexity to gut–microbe–environment interactions. These findings provide new insights into the assembly of the gut microbiome in wild salmon populations.

Heat-stressed *Aspergillus terreus* strain as a potential candidate for improving crop performance

Hazzouri K¹, Protcer M¹, Sudalaimuthuasari N¹, Amiri K¹

¹Kcgeb

POSTER SESSION 1 - **P01.076**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In this study, thermotolerant and plant growth-promoting endophytic fungi were isolated from *Citrullus colocynthis*, a wild melon native to arid desert environments. Among the isolates, DMF1, identified as *Aspergillus terreus*, demonstrated strong plant growth-promoting traits, including significantly elevated indole-3-acetic acid (IAA) production and phosphate solubilization when cultured under elevated temperatures (40+ °C), compared to control conditions (28 °C). Tomato seeds and seedlings inoculated with *A. terreus* DMF1 culture extract exposed to high temperature (40+ °C) exhibited significantly improved root length, chlorophyll content, water use efficiency and stomatal conductance compared to controls. RNA sequencing (RNA-seq) from DMF1 control (28 °C) and heat-stressed (40+ °C) was consistent with notable upregulation of Nitrilase and alkaline phosphatase genes under heat stress. Nitrilase is involved in IAA biosynthesis, contributing to auxin homeostasis and root development, while alkaline phosphatase plays a central role in phosphate mobilization and solubilization. These results provide molecular evidence that

DMF1 under elevated temperatures enhances specific transcriptional responses associated with plant growth regulation. Metabolite analysis revealed significant accumulation of cyclitol derivatives, including inositol and its phosphorylated forms. Inositol derivatives, particularly inositol polyphosphates and pyrophosphates, are recognized as multifunctional signaling molecules involved in phosphate storage, cellular stress responses, and hormone crosstalk. Notably, these metabolites are known to influence auxin perception and signal transduction, with potential downstream effects on root architecture, especially promoting primary root elongation under adverse conditions consistent with our in vivo findings. Our findings underscore the role of plant-endophyte interactions in helping the desert melon *Citrullus colocynthis* endure harsh desert conditions. They also highlight the potential of heat-stressed *Aspergillus terreus* DMF1—isolated from a naturally heat-adapted host—as a promising bioinoculant candidate for enhancing crop performance and sustainable agriculture under climate change.

Honey as a window into the honey bee microbiome : shedding light into diversity and host–environment interactions

Birgel J¹, Hoede C^{2,3}, Canale-Tabet K¹, Leroy T¹

¹GenPhySE, Université de Toulouse, INRAE, ENVT, ²Université de Toulouse, INRAE, BioinfOmics, GenoToul Bioinformatics Facility, ³Université de Toulouse, INRAE, UR 875 MIAT

*POSTER SESSION 1 - **P01.084**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Bees are composed of over 20000 species worldwide, playing a key role in pollination. Among them, only about ten species are capable of honey production, including the well-known *Apis mellifera*. Originally from Africa, the Middle East and Europe, this species includes about thirty subspecies, some of which have been extensively used and exported for the needs of the beekeeping sector. As a consequence, *Apis mellifera* is now present on every continent, except in Antarctica. Therefore, honey bees showed a remarkable capacity of adaptation and evolved successfully in a wide range of contrasting environments and climates. Furthermore, due to anthropic activities such as intensive agricultural practices (pesticides, insecticides) and climate change, honey bees have to face rapid changes and new emerging damaging diseases (*Varroa destructor* mite, small hive beetle...). Currently, these factors lead to an increased mortality of honey bees which will strongly impact the sustainability of the food production system and the overall ecosystems. To understand how bees have adapted to these varying environmental constraints and how they continue to face the new threats posed by global environmental change, we used honeys as an indirect proxy to characterize the composition and the role of their microbiomes. To this purpose, we analysed shotgun sequencing data coming from 121 honeys, corresponding to a large variety of geographic origins and subspecies of bees (including 107 honeys from all over Europe, 8 from Africa and 6 from other locations worldwide). These data were generated on 68 samples within our laboratory using MiSeq technology, while 53 samples come from open-access public databases, sequenced by a wider range of techniques (NextSeq, HiSeq, NovaSeq, BGISEQ). Overall, most samples show a low to medium depth (1.8 million reads on average for

117 samples), while a few were sequenced at greater depth (32 million reads on average for 4 samples). Among our samples, 22 honeys come from hives in France that have been furthermore monitored for their varroa mite infestation level. For the majority of our samples, we also know which plants were used for honey production, providing additional information for data interpretation.

To characterize the composition of honey's microbiota, we used a dedicated metagenomics pipeline (metaWGS) that allows us to access the taxonomic and functional diversity of the microbial communities. This flexible pipeline contains a succession of steps that allow the assembly, the binning and annotation of contigs as well as reconstruction of Metagenome Assembled Genomes (MAGs) at high quality. Through these analyses, we were able to assign a wide range of microorganisms, both eukaryotic and prokaryotic, that are present in honeys. In addition to the identification and provision of new genomic resources, we characterized the proportion of this microbial diversity using abundance tables, so as to be able to assess microbial variation in relation to the host genetic background, differences in climates or other environmental factors. Although my doctoral work is intended to be complemented with additional samples, particularly from more divergent bee species (including other species or even genera), the results already suggest variations in communities. We will particularly discuss the promise of genomic and metagenomic approaches applied to beehive products to help understand how microbiomes have co-evolved with their host, and how this evolutionary process can be associated with the long-term maintenance of bees in the natural and agricultural ecosystems in a global change context.

Human oral microbiome and its impact on dental caries across the last 7000 years in Anatolia

Aktürk Ş¹, Kazancı D^{1,2}, Vural K², Özer F¹, Yet İ¹, Somel M², Kırdök E³, Erdal Y¹, Kılınç G¹

¹Hacettepe University, ²Middle East Technical University, ³Mersin University

POSTER SESSION 1 - **P01.095**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Microbial communities play a vital role in host health, adaptation, and ecological flexibility, with the oral microbiome being one of the most diverse and dynamic ecosystems in humans. The composition of this microbiome is shaped by complex interactions between genetics, environmental factors, and diet. Among the health conditions deeply linked to oral microbiome dynamics, dental caries stands as one of the most common chronic diseases in human history. Its microbial origins lie in the breakdown of a balanced health-associated community into one dominated by acid-producing and acid-tolerant species capable of demineralizing tooth enamel — a transformation often driven by carbohydrate-rich diets and changing oral hygiene behaviors. As ancient human groups experienced local dietary shifts combined with broader cultural and demographic transformations, a similar complex interplay likely shaped the structure and diversity of their oral microbiomes across generations. Such transformations may also have altered microbial communities in ways that contributed to the emergence and persistence of caries. Southwest Eurasia may be particularly interesting as it underwent a transition to agriculture millennia earlier than many other regions. Despite the recognition of the oral microbiome's role in health and disease in modern studies, little is known about how these microbial communities evolved over long periods in response to the shifting ecological, dietary, and cultural environments of ancient populations in this region. Here, we investigate how long-term shifts in the human oral microbiome contributed to the increased prevalence of dental caries over a 7,000 year-long time span in Anatolia.

Materials and Methods: In this study, we examined the human oral microbiome associated with both dental health and caries in ancient Anatolian populations. We analyze ancient metagenomes from 56 individuals,

representing three distinct populations, spanning approximately 7,000 years from the Late Neolithic to the Medieval period. We screened 60 individuals from three distinct archaeological settlements based on their anthropometric characteristics and selected 56 individuals (16 Late Neolithic, 20 Middle Age, and 20 Medieval Period) with and without dental caries from each region. We sampled dental calculus from all available teeth per individual to maximize microbial DNA recovery and extracted DNA to prepare double-stranded genomic libraries for downstream analysis. We produced 10,000,000 paired-end sequencing reads per individual using Illumina Novaseq X platform. By analyzing sequencing reads, we reconstructed temporal microbial genomic profiles over the last 7,000 years. The bioinformatic pipeline aMeta was applied for taxonomic classification using k-mer signatures and alignment-based approaches, allowing us to confidently authenticate ancient DNA and accurately characterize the microbial community composition. Beyond taxonomic profiling, we calculated alpha and beta diversity metrics to assess within- and between-individual variation and track shifts in microbial community structure over time.

Results and Conclusions: Through this research, we provide a population-specific and time-resolved perspective on the dynamic relationship between the oral microbiome and human health. Our results highlight the evolutionary persistence of caries-associated microbial patterns and reveal how host health status, subsistence practices, and environmental factors collectively shaped the oral microbiome over millennia. This work further traces long-term changes in microbial community structure and explores how shifts in diet and lifestyle may have driven transitions between health-associated and caries-associated microbial profiles over thousands of years.

Impact of the presence of Varroa Mite on the Microbiota of *Apis mellifera* and *Bombus terrestris*

Borveto F¹, Wilfert L¹

¹Institute Of Evolutionary Ecology And Conservation Genomics - Ulm University

POSTER SESSION 1 - P01.106, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Corbiculate bees such as Honey bees (*Apis mellifera*) and the Buff-tailed bumblebee (*Bombus terrestris*) harbor a consistent microbiome composed of relatively few species that are host specific. It has been shown that they play an important role in bee health not only in nutrition but also in the immune functions.

A. mellifera hives in Europe are commonly infested by the Varroa destructor mite, vector of several bee pathogens such as Deformed wing virus (DWV). The association of these two can lead to an increased viral load in foraging bees which are in regular contact with wild bumblebees.

In this study, we aim to explore the interactions between the honey bee specific parasite Varroa, viral prevalence and the microbiome of managed and wild bee populations. Our dataset consists of *A. mellifera* and *B. terrestris* samples from varroa infested and varroa free sites. Results from 16s rRNA sequencing reveal correlations between changes in the microbiome and the presence of pathogens in honey bees, namely *Pseudomonas*, *Wolbachia* and SBPV. While in bumblebees, we observe a strong effect of the presence of Varroa at the sampling site, and prevalence of DWV-B, despite the fact that Varroa is a honey bee specific parasite.

Integrative multi-omic analysis reveals oral microbiome-metabolome signatures of obesity

Jha A¹, Shibl A, Denekew T, Ahmad A, Abdelrazig S, Leonor C, Utenova L, Zhang G, AbdelBaqi M, Malla Y, Arshad M, Arnoux M, Drou N, Abdulle A, Ali R, Amin S, Idaghdour Y

POSTER SESSION 1 - **P01.092**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Obesity is a major global health challenge and a leading risk factor for cardiometabolic disorders. The global surge in obesity, driven by industrialization and the widespread consumption of low-fiber, ultra-processed food, highlight an urgent need for deeper biological insights. While the gut microbiome has been studied in the context of obesity, the contribution of the oral microbiome—the second largest microbial ecosystem in the human body—remains largely underexplored. Here, we report findings from a deeply-phenotyped prospective-cohort of 628 Emirati adults, leveraging amplicon sequencing of mouthwash samples and multi-omics profiling and functional and metabolic activity analysis of 97 obese individuals and 95 matched controls, making this the most comprehensive multi-omics analysis of the oral microbiome. We identified significant differences in oral microbial diversity, composition, functional pathways, and metabolic profiles between obese and non-obese groups. Integrated multi-omics analysis of the 192 matched metagenomes and metabolome samples uncovered significant metabolic reprogramming and altered energy regulation in obesity. Specifically, the oral

microbiome of obese participants were enriched for the proinflammatory *Streptococcus parasanguinis* and *Actinomyces oris*, and the lactate-producing *Oribacterium sinus*. Many microbial pathways involved in dietary carbohydrate metabolism, histidine degradation, as well as the production of obesogenic biomolecules were also enriched in obese participants; however, B-vitamin and heme production pathways were depleted. Consequently, metabolites resulting from these pathways such as lactate, histidine derivatives, choline, uridine, and uracil were elevated in obesity. These consistent microbiome-metabolite shifts were strongly associated with prominent obesity-associated cardiometabolic markers, including serum triglycerides and alkaline phosphatases. These findings provide the most comprehensive insights into how disrupted microbial-metabolic cross-talk in the oral cavity may contribute to obesity and related cardiometabolic disease risk, underscoring the potential of targeting of oral microbiome-host interactions as a novel avenue for obesity prevention and intervention.

Intestinal tissue remodeling as a key adaptation to starvation in cave-dwelling fish

Santacruz A^{1,2}, Champeong D², McClain M², Rohner N^{1,2}

¹University of Münster, ²Stowers Institute for Medical Research

POSTER SESSION 1 - **P01.110**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Food availability is one of the major evolutionary forces driving species evolution. In environments with limited nutrient availability—such as caves—cave-dwelling species have evolved unique adaptations to survive. The Mexican cavefish (*Astyanax mexicanus*) has repeatedly colonized subterranean environments, evolving metabolic and immune strategies that enable it to withstand long-term food deprivation. In contrast, its surface-dwelling ecotype displays relatively limited starvation tolerance. Given the gut's central role as the interface between the host and ingested nutrients, we investigated how intestinal tissue and its symbionts respond to prolonged starvation in both cavefish and surface fish. We combined ultrastructural morphological analysis, metagenomics, and single-cell transcriptomics to characterize the intestines of cavefish and surface fish under both starved and non-starved

conditions, at two and four months of complete food deprivation. Our results revealed that, under homeostatic conditions, cavefish exhibit higher activity of absorptive cells compared to surface fish, highlighting their enhanced metabolic capacity. Under starvation, surface fish show disruption of the mucosal landscape and impairments in intestinal integrity, whereas cavefish maintain intestinal structure even in the absence of food. We show that, even under controlled laboratory conditions, cavefish and surface fish harbor distinct microbial communities that are reassembled during starvation. These findings highlight cavefish as a powerful evolutionary model to investigate how dietary changes shape organismal evolution and establish them as a valuable natural system for studying prevalent human diseases that affect intestinal integrity.

Leveraging metagenomics to characterize the gut microbiome of caribou (*Rangifer tarandus*) for conservation.

POSTER SESSION 1 - P01.093, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The gut microbiome is increasingly recognized as a key component of wildlife ecology and conservation, offering insights into host health, diet, adaptation, and responses to environmental change. This is especially important for threatened species like the caribou (*Rangifer tarandus*), whose herds in Western Canada are listed as species of special concern or threatened under the federal Canadian Species at Risk Act (SARA), and are declining due to habitat fragmentation, increased predation, and reduced connectivity. However, the microbial dimension of caribou health remains largely unexplored. In this study, we conducted the first large-scale metagenomic survey of caribou gut microbiota to investigate how host genetics, environmental context, and foraging behavior shape microbial diversity and function across herds. Using shallow shotgun sequencing, we analyzed 184 fecal samples from 21 caribou herds across British Columbia. We show that a sequencing depth of approximately 500,000 paired-end reads per sample is sufficient to resolve microbiome composition and functional potential with cost-effectiveness. Our bioinformatic analyses revealed a conserved core microbiome across herds, primarily composed of bacterial taxa associated with fiber degradation and host metabolic support. However, microbial community structure differed significantly between northern and southern herds, with southern, more

genetically isolated herds exhibiting markedly lower alpha diversity and distinct taxonomic profiles. We found that genetic differentiation better predicted microbiome composition than geographical distance. We discovered that smaller, inbred and isolated herds displayed markedly reduced microbiome diversity. Pathogen screening identified low-frequency but concerning occurrences of potential pathogens such as *Listeria monocytogenes* in certain herds, emphasizing the utility of microbiome data for wildlife health monitoring. Functionally, the microbiome exhibited high metabolic redundancy, but certain pathways were enriched in specific herds. Notably, southern herds displayed enhanced microbial capacities for starch degradation, an adaptation likely linked to a winter diet dominated by arboreal lichens. These localized functional adaptations highlight a possible link between microbial communities and caribou dietary specialization and underscore the potential for microbiome plasticity to buffer environmental challenges. By integrating microbiome data with host genomic and ecological information, this study provides a novel framework for understanding caribou health and adaptation at the microbial level. Our results highlight the gut microbiome as a sensitive biomarker for conservation applications to support decision-making around herd management, habitat restoration, and translocation strategies.

Linking phenotypic responses and advanced metagenomic techniques in *Daphnia magna* in response to combined environmental stresses

Yefimak K^{1,2}, Decaestecker E¹, Van Belleghem S²

¹MicrobiomeEcoEvo group IRF Life Sciences KULAK, ²Lab of Eco-Evolutionary Genomics Leuven

POSTER SESSION 1 - P01.075, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Natural populations are increasingly exposed to a range of stressors including those linked to agricultural intensification, such as pesticide exposure as well as ecological pressures like altered predator–prey dynamics. These stressors often do not act alone but interact in complex ways, potentially amplifying their negative effects on freshwater ecosystems. The role of host-associated microbiomes in mediating stress tolerance is increasingly recognized, yet their contribution to responses in organisms under combined environmental stressors remains underexplored. This research investigates the microbiome's role in shaping phenotypic traits in *Daphnia magna*, an important freshwater organism, when exposed to both chlorpyrifos (an organophosphate insecticide) and fish kairomones (a predation cue). The experiment focuses on linking these phenotypic responses to shifts in microbiome composition and function, potentially influencing stress tolerance.

Daphnia clones were collected from twenty ponds with varying pesticide exposure and predation pressure histories. In the life history experiment the *Daphnia* clones were exposed to four treatments: control, chlorpyrifos, fish kairomones, and combined exposure, replicated three times. Age at maturity, reproductive output, body size, spine length and survival, were measured to assess phenotypic responses to individual and combined stressors.

This experiment aimed to determine an optimal pesticide and fish kairomones concentration based on one clone of each of four pond type, for a bigger follow-up study involving six clones from each of the twenty ponds. The goal was to identify a pesticide concentration that would provide a balance between survival and stress to detect meaningful differences, especially in combination with fish exposure. To achieve this, a range of pesticide concentrations was tested,

ranging from 0.1 to 1.4 µg/L, including combinations with fish. Based on the results, 0.2 µg/L chlorpyrifos is the optimal concentration together with 0.2 fish/L. Results also revealed significant clone-specific and stressor-dependent phenotypic responses. Across all clones, fish-exposed individuals produced larger clutches on average. Prior exposure to fish appears to provide a slight survival advantage, particularly under combined stressor conditions (pesticide + fish). In contrast, clones with no prior exposure to either stressor are more vulnerable to pesticide exposure, showing limited resilience.

While microbiome samples have not yet been collected, the follow-up phase of this study will involve *Daphnia* samples for metagenomics and microbial profiling at the end of the experiment. These microbiome analyses will help identify bacterial taxa and functional genes, such as those involved in pesticide degradation or stress resistance, that correlate with observed variation in phenotypic traits under combined environmental stressors. A novel aspect would be the application of adaptive Nanopore sequencing in metagenomics for selective microbial DNA enrichment, aimed at reducing host DNA contamination. Protocols are optimized using different DNA extraction kits and microbial DNA enrichment kits. These methods will be compared with traditional Nanopore sequencing workflows. By the time of the conference, preliminary results on the effectiveness of adaptive Nanopore sequencing will be available, which is expected to significantly improve microbial detection, particularly for low-abundance taxa.

By integrating phenotypic data with advanced metagenomic techniques, this study aims to provide new insights into the role of microbiomes in response to environmental stressors in *Daphnia magna*.

Metagenomic insights into the ageing gut microbiome in a natural population

Lee C¹, Worsley S¹, Davies C¹, Silan E², Burke T³, Komdeur J⁴, Hildebrand F², Dugdale H⁴, Richardson D^{1,5}

¹School of Biological Sciences, University Of East Anglia, ²Quadram Institute, ³Ecology and Evolutionary Biology, School of Biosciences, University of Sheffield, ⁴Groningen Institute for Evolutionary Life Sciences (GELIFES), University of Groningen, ⁵Nature Seychelles

POSTER SESSION 1 - P01.072, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

While the influence of the gut microbiome (GM) on human health has been extensively researched, its impact on ageing and senescence in wild animal populations remains unclear. Indeed, studies addressing such questions in wild populations have yielded conflicting findings. Part of the problem is that acquiring the lifelong longitudinal data on individuals required to gain resolution on ageing effects is extremely challenging. I will address these limitations using a population of Seychelles warblers (*Acrocephalus sechellensis*) and analysing individual-based longitudinal metagenomic GM data to investigate how functional GM diversity, composition, and stability are associated with host age and senescence. Studies on humans suggest a complex interplay between GM and host senescence,

where age-related declines in physiological function appear to be linked to shifts in microbial composition and reduced GM stability. Therefore, we hypothesise that GM functionality will remain stable for most of adult life but differ significantly in late life, and especially just before death, as a result of host senescence. By using a combination of metagenomics and repeated sampling of individuals, we offer a more nuanced and potentially more accurate analysis compared to previous metabarcoding studies. In future work, this data will be analysed alongside host genomes to better understand how inbreeding (assessed through runs of homozygosity) interacts with the GM to influence host senescence trajectories.

Microbiome diversity in a successful urban bird

Kamiński M¹, Jeziorski S¹, Skóra M², Bożyk B², Strapagiel D², Minias P¹

¹University of Lodz, Faculty of Biology and Environmental Protection, Department of Biodiversity Studies and Bioeducation, ²University of Lodz, Faculty of Biology and Environmental Protection, Centre for Digital Biology and Biomedical Science – Biobank Lodz

POSTER SESSION 1 - P01.107, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The expansion of urbanized areas severely transforms natural habitats and selective pressures faced by animals. However, some species function remarkably well within a man-made environment. A paragon example of an urban bird is the feral pigeon *Columba livia domestica*, which inhabits towns and cities around the globe, where it often thrives in extreme population densities. Feral pigeons show remarkable adaptations to urban landscape, but it remains unexplored how different components of this urban life modulate gut microbiome. The gut microbiome performs a number of roles, affecting host physiology, and consequently – its fitness. High level of sociality and frequent interactions with conspecifics are considered to be important factors leading to an increased gut microbiome diversity, due to facilitated horizontal transmission.

Materials and methods: We aimed to investigate how habitat urbanization and conspecific density can influence the taxonomic and functional diversity of the gut microbiome in a well-adapted urban bird, the feral pigeon. To address these questions, we sampled 200 adult feral pigeons across the gradients of habitat urbanization and pigeon population density in five large cities in Poland. Using the meta-barcoding approach based on the high-throughput 16S rRNA sequencing, we identified microbial assemblages in collected fecal samples. We calculated alpha (Shannon diversity and ASV richness) and beta (Jaccard distances) diversity indices. We also used the FAPROTAX database to assign functional profiles to the microbial taxa and to analyze

shifts in functional diversity of the gut microbiome. We tested the associations of habitat urbanization and pigeon population density gradients with microbiome diversity measures using GLMM models (alpha and functional diversity) and PERMANOVA (beta diversity).

Results: We found significant differences in taxonomic composition of pigeon gut microbiome between areas with different levels of urbanization and different host population density. We have not observed associations of pigeon population density with alpha microbiome diversity, however, we found a negative relationship between habitat urbanization score and ASV richness. When we investigated 10 most abundant functional groups, we found that none of them was associated with population density. Microbial groups associated with human and mammal gut, and, most importantly, human pathogens increased in relative abundance along urbanization gradient.

Conclusions: Our study was among the first addressing the links of bird sociality and group size with gut microbiome diversity in urban ecology context. Contrary to the expectations, we found little evidence of relationship between microbiome diversity and host population density. Interestingly, we detected changes in both ASV richness and functional diversity mediated by habitat urbanization. Especially, human pathogens were more abundant in more heavily urbanized habitats, which highlights the role of feral pigeons as pathogen vectors.

Rapid changes in the gut microbiome revealed by repeated short-term sampling in a captive guppy population

Herdegen Radwan M¹, Wilanowska P¹

¹Adam Mickiewicz University

*POSTER SESSION 1 - **P01.091**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

With the growing number of studies reporting associations between gut microbiome and diverse aspects of their hosts life, from physiology to behaviour and cognition, it becomes crucial to understand the dynamics of microbiome changes within individuals. While repeated sampling of individuals is often challenging, relying on a single sample - the most common practice - requires validation through evidence of gut microbiome stability. Here, we used a captive guppy population to assess short-term gut microbiome stability at the individual level, based on fecal samples collected over a two-week period from six fish. Bacterial taxa were sequenced and identified based on the 16S rRNA gene barcoding. We found substantial changes in microbial composition within few days,

mostly driven by rapid turnover of many rare taxa. At the same time, a 'core' microbiome could be identified for each fish, composed of very few abundant taxa. Interestingly, while the 'core' taxa mostly overlapped between individuals, there was significant inter-individual variance in their abundances. Taken together, these results suggest that even under stable environmental conditions the microbial composition of an animal's gut can undergo dynamic changes over short periods of time, without precluding substantial inter-individual variation in the gut microbiome. Thus, a careful analysis of the stability of a study organism's microbiome may help to determine the level of resolution required to conduct a reliable association study.

Reproductive Success Dependencies of Gut Microbiome: Insights from a Wild Population of Blue Tits

Cendrowska M¹, Drobnia S¹

¹Jagiellonian University

*POSTER SESSION 1 - **P01.100**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Gut microbiota composition and diversity are increasingly recognized as key factors influencing host fitness and reproductive outcomes in avian species. In this study, we investigated the relationship between gut microbiome characteristics and reproductive success in a wild population of blue tits (*Cyanistes caeruleus*) breeding on the island of Gotland, Sweden. Cloacal swabs were collected from adult individuals during two breeding seasons, with microbiome profiling performed via 16S rRNA sequencing. Alpha diversity metrics and beta diversity were analyzed in relation

to clutch size, fledgling success, and average nestlings' tarsus length (as a measure of offspring quality). The study provides novel evidence that gut microbiome may act as a proximate mechanism predicting reproductive success in passerines. A portion of broods included in our study also took part in a brood size manipulation experiment. Including this component in analyses indicates that the correlation between fitness components and microbiome composition metrics may be environmentally dependent.

Sex-Specific Evolution of Host-Parasite Interactions: The Interplay Between Host Genetics and Microbiome in the Immune Response in Trinidadian Guppies

Kramp R¹, Janecka M^{1,5}, Tardent N^{3,4}, Jokela J^{3,4}, Kohl K¹, Stephenson J^{1,2,3,4}

POSTER SESSION 1 - P01.069, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

1. Host responses to parasite infection involve several interacting systems. Host genetics determine much of the response, but it is increasingly clear that the host-associated microbiome also plays a role. Genetically determined systems and the microbiome can also interact; for example, the microbiome can modulate the host immune response, and vice versa. However, it remains unclear how such interactions between the host immune system and the microbiome may influence the host's overall response to parasites.

2. Host sex is an important source of variation in both immune response and the microbiome across systems, so interactions between them may also therefore differ between males and females, potentially explaining sex-specificity in response to parasites.

3. To investigate how host genetics and the microbiome interact to shape responses to parasites, we selected Trinidadian guppies (*Poecilia reticulata*) with low and high parasite resistance to the specialist ectoparasite *Gyrodactylus turnbulli*. Following experimental infection, we used the 30% of guppies with the lowest parasite

load to found the resistant line, the 30% with the highest load to found the susceptible line, and randomly chosen uninfected fish to found the control line. After 3-6 generations of breeding without parasites, we sampled the skin-associated microbiome and then infected fish from each line. We applied machine-learning to identify bacterial community types across lines and evaluated how selection line and community type explained variations in infection severity.

4. Our findings showed that among females, the resistant line had significantly lower infection severity, while the susceptible line had higher infection severity than other lines. Interestingly, females in the resistant line lost more mass per parasite, i.e., exhibited lower parasite tolerance, than in the control or susceptible lines. Among males, the susceptible line experienced higher infection severity than the other lines, but there was no difference between the resistant and control lines.

5. We found that the microbiome and host genetics independently explain similar variation in infection severity, highlighting the microbiome's active role in host-parasite interactions. Our results also indicate sex specificity in the evolution of host defenses.

Shaping Metabolism Through the Microbiome: Genetic Constraints on Host Plasticity in a Model of Obesity

Curtis-Joseph N¹, Belenky P²

¹Brown University - Department of Molecular & Cellular Biology & Biochemistry, ²Brown University - Department of Molecular Microbiology and Immunology

POSTER SESSION 1 - P01.071, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Obesity and metabolic disorders pose major global public health challenges, with rising rates of metabolic syndrome across populations. Growing evidence indicates the gut microbiome acts as a critical mediator of host metabolic flexibility, influencing energy homeostasis and metabolic function. The db/db mouse model, featuring a leptin receptor gene mutation, displays hyperphagia, obesity, and hyperglycemia, providing an ideal system for studying how host genetic backgrounds interact with microbiome composition to shape metabolic outcomes. While correlations between gut microbiota and metabolic phenotypes are established, the mechanisms through which microbial communities enable metabolic adaptation remain poorly understood. Antibiotic treatment offers a valuable tool for gut microbiome modulation, allowing investigation of how microbial community restructuring impacts host metabolism. Early-life represents a critical developmental window when microbiome disruptions can fundamentally reprogram host metabolism, suggesting the microbiome's role in developmental programming.

Materials & Methods: We hypothesized that pre- and post-natal antibiotic treatment would restructure gut microbiome composition in db/db mice, enhancing metabolic resilience and improving outcomes. We bred db/b6 mice to produce homozygous db/db and heterozygous db/b6 offspring. Pregnant dams received either regular water or an antibiotic cocktail from pregnancy through offspring weaning until 8 weeks of age, creating eight experimental groups with sex and treatment variables. We monitored metabolic parameters and collected samples weekly

until sacrifice at 15 weeks. Analyses included energy harvesting efficiency measurements, inflammatory marker profiling, intestinal transcriptomics, and microbial community analysis.

Results: Our findings revealed that antibiotic-induced microbiome restructuring significantly enhanced metabolic health in homozygous db/db mice, demonstrating the microbiome's capacity to modify genetic predisposition. Antibiotic-treated homozygous mice exhibited improved metabolic parameters, such as reduced weight gain and better glucose homeostasis. Notably, heterozygous mice showed no significant response to identical treatment, highlighting how host genetic background constrains microbiome-mediated metabolic effects. Preliminary data suggest antibiotic treatment altered microbial community function, reducing energy extraction efficiency and shifting bacterial composition from predominantly Muribaculaceae and Sutterellaceae toward Lactobacillaceae and Bacteroidaceae in treated homozygous mice. These findings demonstrate the microbiome's role as a key mediator between host genetics and metabolism, capable of buffering genetic predisposition to obesity when modified during critical developmental windows.

Conclusion: This work provides compelling evidence that the gut microbiome contributes significantly to host metabolic plasticity in a genotype-dependent manner. Our findings highlight the potential for early-life microbial modulation to buffer genetic risk, and our ongoing research aims to identify specific microbial and metabolite mediators of these effects to inform targeted interventions for metabolic health.

Sustainable antimicrobial management in the burying beetle external microbiome

Duxbury S¹, Jardine M¹, Price T¹, Studholme D², Raymond B¹, Royle N¹

¹Centre for Ecology and Conservation, University Of Exeter, ²Biosciences, University of Exeter

POSTER SESSION 1 - P01.097, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Burying beetles (*Nicrophorus vespilloides*) exhibit a parental care system whereby they process small vertebrate carcasses as a nutritious resource to raise their larvae. This ephemeral resource must be defended against microbial degraders that colonise the carcass and surrounding soil. *N. vespilloides* is known to produce a diverse suite of around 40 narrow-spectrum antimicrobial peptides (AMPs) in secretions onto the carcass. These AMPs are predicted to suppress growth of target microbial competitors, whilst preserving beneficial microbes, originating from the carcass or beetle symbionts, that aid beetle reproduction and survival and larval development. The production of these AMPs in varying amounts and seeding of commensals may explain how resistance evolution in competitors has been avoided over millions of years of microbial management. Whilst there is some evidence for plasticity in AMPs production in response to perturbations in the levels and diversity of microbial competitors, the exact mechanisms have not been studied. To manipulate microbial competition on mouse carcasses, we set up three conditions in the laboratory using (i) antibiotic-treated or (ii) 'fresh' or (iii) 'smelly' carcasses, representing progressively advanced states of decomposition and decreasing resource quality. Beetle populations (lab-reared from the wild) were paired for reproduction and females were then exposed to these carcass types for their developmental cycle. Upon appearance of larvae, carcass 'pit' microbiomes were sampled and anal

secretions from female beetles were collected for quantitative proteomics. Reproductive output across treatments was measured. In line with predicted treatment effects on resource quality, offspring production (larval mass and brood size) decreased on 'smelly' carcasses, whilst antibiotic treatment improved reproductive output. Antibiotics reduced abundance of bacteria from the genus *Clostridium* in the managed microbiome. Across treatments, beetle processing of carcasses reduced abundance of bacteria from the *Lysinibacillus*, *Bacillus* and *Citrobacter* genera and increased bacterial abundance from the *Vagococcus* genus. Key AMPs associated with beetle immunity were quantified in the proteome of secretions (thaumatin-4 and c-lysozyme 2), with sustained production across the microbiome perturbation treatments. Proteome structure showed greater between-sample (beetle-family level) variance for secretions produced on 'smelly' carcasses as opposed to antibiotic-treated. This work shows that resource quality impacts beetle reproductive success; however, beetles can successfully manipulate their external microbiomes and plastically respond to perturbations in microbial competitors. Unlocking these strategies of resistance management will have broader implications both for understanding the role of plasticity in social evolution and in developing strategies to tackle the antibiotic resistance crisis in clinical settings.

Symbiotic communities of *Planococcus ficus* (vine mealybug) from two vineyards varieties

SANTOS GARCIA D¹, Genson G¹, Mozes-Daube N², Iasur Kruh L³, Zchori-Fein E²

¹CBGP INRAE UMR1062, ²Department of Entomology, ARO Newe-Ya'ar Research Center, ³ORT Braude College of Engineering

POSTER SESSION 1 - **P01.109**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The vine mealybug (*Planococcus ficus*, Hemiptera: Sternorrhyncha: Pseudococcidae) is a phloem-feeding insect and a major pest of grapevines (*Vitis vinifera*). It is the principal vector of Grapevine leafroll-associated virus 3 (GLRaV-3), the most widespread virus affecting vineyards. GLRaV-3 has a positive-sense RNA genome and is transmitted in a semipersistent manner. Notably, when *P. ficus* is reared on potato plants under laboratory conditions, it loses its ability to transmit GLRaV-3—an effect likely linked to both the absence of the natural grapevine host and changes in its gut symbiotic community.

Recent findings suggest that certain insect symbionts can interfere with the transmission of plant viruses, highlighting the importance of studying the gut microbiota of *P. ficus*. To investigate the biodiversity and dynamics of its gut symbionts, we sampled mealybugs from grapevines showing mild and severe GLRaV-3 symptoms and analyzed their associated microbial communities.

Materials and Methods: Mealybugs were collected from two vineyards (Dalton and Ein Zeitim), located 1.7 km apart and planted with different grapevine cultivars. From each vineyard, six samples were obtained from vines showing visible GLRaV-3 symptoms. Each sample included a grape bunch infested with mealybugs and five leaves from the same plant. A subset of mealybugs was transferred to virus-free grapevine plants in the laboratory, where they were allowed to reproduce for one generation.

Total DNA was extracted from surface-sterilized mealybugs from both field and laboratory colonies, and 16S rRNA amplicon sequencing was performed to assess bacterial community composition. In parallel, mealybugs were homogenized and plated on various culture media under aerobic and anaerobic conditions to isolate cultivable bacteria. Emerging colonies were identified through colony PCR and Sanger sequencing of the 16S rRNA gene. Presence of

specific bacteria in leaf tissue was confirmed by PCR using species-specific primers.

Additionally, one pooled sample from each vineyard underwent Illumina whole-genome shotgun sequencing. Established pipelines were used to assemble and annotate bacterial metagenome-assembled genomes (MAGs), which were further analyzed for metabolic potential and virulence factors. Average Nucleotide Identity (ANI) and phylogenetic analyses were conducted on amplicons, cultured isolates, and MAGs to determine their evolutionary relationships.

Results: Mitochondrial cytochrome oxidase I sequences revealed distinct haplotypes between the two mealybug populations. Both carried the obligate symbionts *Tremblaya princeps* and *Moranella endobia*. Mealybugs from Dalton had high loads of *Serratia symbiotica*, while those from Ein Zeitim harbored an abundant but previously undescribed *Acetobacteraceae* species. Both bacteria were nearly absent after one laboratory generation, suggesting they are environmentally acquired. Their detection in grapevine leaves supports this hypothesis.

We successfully cultured *S. symbiotica*, later confirmed as strain CWBI-2.3 by ANI and phylogenetic analysis. The *Acetobacteraceae* isolate appears to represent a novel genus related to known bee gut symbionts. Comparative genomic analyses show both bacteria cluster with facultative insect symbionts and possess pathways for biotin synthesis, a vitamin absent from vine phloem.

Conclusions: Our preliminary results suggest that *S. symbiotica* and the novel *Acetobacteraceae* species are environmentally acquired, plant-associated bacteria capable of colonizing *P. ficus*. Their potential role in supplementing biotin suggests a fitness benefit to the insect. Moreover, the colonization capacity of *S. symbiotica* opens promising avenues for microbiome-based pest control strategies.

Testing for genetic differences in fitness across an environmental gradient using germ-free hosts to incorporate “local” microbiomes

Acerbi G^{1,2}

¹Institute for Freshwater Ecology and Inland Fisheries (IGB), ²Freie Universität

POSTER SESSION 1 - P01.088, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Urbanisation is accelerating globally, causing adverse ecological conditions and disrupting ecosystem functioning. Urban ponds, increasingly implemented as nature-based solutions to mitigate climate-related impacts, are often exposed to harmful pollutants due to increased urban runoff. Zooplankton are typical inhabitants of urban ponds, and are key to the top-down control of algae, suppressing (toxic) algal blooms. As a result, disruption of the ecological functioning of zooplankton due to chemical pollution introduces risk for the ecological integrity of urban ponds. While recent work has demonstrated genetic adaptation in water flea *Daphnia magna* to urban stressors, including pollutants, the role of the microbiome in mediating tolerance has not been tested. Standard common garden experiments typically involve genotypes that have been bred in the laboratory and thus carry laboratory-shaped microbiomes. Here we use 18 germ-free *Daphnia* genotypes sourced from six ponds across a pronounced urbanization gradient in Berlin-Brandenburg area. These were exposed to field-collected

water – containing both the microbial communities and chemical signatures - of their own habitat or the habitat of other populations. This design allows us to test whether *Daphnia* genotypes differ in their fitness when exposed to different media and associated microbial communities and whether *Daphnia* genotype or medium-microbial community complex is the most important determinant of fitness. First analyses reveal that the origin of the environmental microbiome complex explains most of the variation in *Daphnia* fitness and mortality, whereas population origin had a much weaker effect. There was, however, a significant ‘population origin × environmental microbiome complex’ effect. Specifically, one highly urban population exhibited increased fitness in the sympatric condition, though this pattern was not a consistent across all populations. Our study underscores that both host genetics and combined effect of microbiome and environment, are key to understand adaptation in changing, urbanized environments.

The gut microbiota of hybrid birds: a possible role in speciation?

Martínez Renau E¹, Zhu Y¹, Cortazar-Chinarro M¹, Qvarnström A¹, Videvall E¹

¹Uppsala University

POSTER SESSION 1 - **P01.089**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

In recent years, it has become increasingly clear that the gut microbiota of animals can be an important determinant of ecological adaptation, even having a significant impact on reproductive success and speciation. The symbiotic microbiome can shape speciation in different ways, and hybridisation provides a unique opportunity to learn more about this process by allowing the study of traits that are important for the build-up of reproductive isolation between genetically diverging populations under natural conditions. Incompatibilities in gut microbiota between hybridising species can lead to both pre-zygotic reproductive barriers by, for instance, influencing mate preferences, and post-zygotic reproductive barriers, by preventing successful hybridisation through negative effects on the hybrids' survival and fitness. In other cases, hybrids may acquire novel traits facilitated by their microbiota, potentially driving divergence and the formation of new species. However, studies of the gut microbiota of hybrids in vertebrates are scarce. As an initial step toward addressing this gap, this study aims to investigate the gut microbiota and diet of two closely related bird species, the pied (*Ficedula hypoleuca*) and collared (*F. albicollis*) flycatchers, and their hybrids. By examining the microbiome using amplicon sequencing of the bacterial

16S rRNA gene and the diet using the insect COI gene, we will explore possible differences in diversity and composition of the two traits among both parental species. Furthermore, we will compare the bacterial community and diet of the parental species with that of the hybrids to assess how distinct these traits are and where they lie in relation to the parental profiles. We hypothesise that the hybrid microbiota will be significantly different from both parental species, although potentially closer to their mothers. In terms of diet, given that both sexes contribute equally to feeding the offspring, we expect the diet composition of hybrids to be intermediate between the two parental species and to show correlations with the microbiome. Based on previous studies, we know that the *Ficedula* hybrids are sterile and experience higher, potentially dysfunctional, metabolic rates. Therefore, we plan to investigate the role of the gut microbiota in host metabolic function in a follow-up part of the study. These results will provide insights into the factors influencing the gut microbiome in the *Ficedula* genus, and how, in turn, microbial composition may influence metabolic function in hybrids, potentially contributing to post-zygotic reproductive barriers between the two species.

The Impacts of Feralization on the Horse Gut Microbiome

Van Well Bergström M¹, Resmini G², Ramírez Rodríguez-Solís D³, Garrido P⁴, Theunissen D², Thulin C⁵, Videvall E¹

¹Uppsala University, ²Linköping University, ³National Museum of Natural Sciences, ⁴Fundación Patrimonio Natural de Castilla y León, ⁵Swedish University of Agricultural Sciences

*POSTER SESSION 1 - **P01.101**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Feralization is a process that occurs when a population of domestic animals returns to wild conditions and can be thought of as a reversion of domestication. Because of the sudden return of both natural and sexual selection, feralization can result in large genetic, morphological, and behavioral changes in animals and their associated microbiota. Hence, when animals become feral, their microbiomes need to adapt as well. Despite intense focus on the microbial changes associated with domestication, the knowledge about how feralization affects the microbiome of animals is limited. Thus, feralization provides a unique opportunity to observe the microbiota responses to selection from a known (domesticated) standpoint. To investigate the impacts of feralization on the horse gut microbiome, fecal samples were collected from feral and domestic specimens of the horse breed Pottoka in Northern and Central Spain in 2023 and 2024. The gut microbiome was sequenced using metabarcoding of the v3-v4 region of the 16S rRNA bacterial gene. Variation in the gut microbiome composition

and diversity was evaluated across individuals and between feral and domestic horses. Furthermore, we investigated differences in the gut microbiota among feral populations, age classes, and sexes. The results indicate that feralization leads to a shift in gut microbiome composition, with lower microbial diversity in the feral horses compared to the domestic horses. These results may be explained by differences in diet, environment, and handling under feral and domestic conditions. We also observed prominent differences in the microbial communities between the feral populations, suggesting strong geographical and environmental influences on the gut microbiota, as well as differences between adults and juveniles. These results enable a better understanding of the process of feralization on the microbiota by providing insights into how the bacterial community in the gut can adapt to novel environments. This knowledge is crucial for understanding adaptation and evolution during the shift from artificial to natural and sexual selection.

The role of the chicken genome in shaping gut microbiota

Becker Burgos M¹, Silva W², Resmini G², Videvall E¹, Wright D²

¹Uppsala University, ²Linköping University

POSTER SESSION 1 - P01.111, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Animals harbor a diverse community of microbes within their intestinal tracts, known as the gut microbiota. It is known to impact host health and fitness, with essential roles related to the immune system, digestion and homeostasis. While numerous extrinsic and intrinsic factors are proven to impact gut microbiota composition, the role of host genetics is less clear. Emerging evidence points to an implication of immune and growth-related host genes and a potential for some microbes to be heritable. However, few studies have investigated the role of host genetics on shaping gut microbiota composition outside humans and model organisms. In this study, we used hologenomic data, to investigate associations between the host genome and

gut microbiota in two free-living island populations of feral chickens. We used 16s rRNA gene sequencing to characterize cecum microbiota variation and whole-genome sequencing to investigate host genomes from 269 feral chickens. Genome-Wide Association analyses (GWAS) were performed using microbiota alpha and beta diversity metrics, in addition to single microbial Amplicon Sequence Variants (ASVs). The results show associations between host genetic regions and microbiota phenotypes. This study will enable a better understanding of the role of the host genome in shaping gut microbiota composition, while also providing a broader insight on disentangling the complexity of host-microbiota interaction in nature.

The wild mammal oral microbiome is shaped by host diet and ecology

POSTER SESSION 1 - P01.083, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Despite increasing interest, the microbiomes of wild animals remain largely undescribed, especially for body sites other than the gut. Shaping these communities on a macroevolutionary time scale, two processes are commonly referenced: a) host-microbiome co-diversification (through vertical transmission) and b) environmental filtering (selection due to environmental conditions). However, their relative importance remains intensely debated, and further study of wild microbiomes is hindered by sampling difficulties. Here, we use dental calculus from museum specimens to explore the evolution of the oral microbiome in wild mammals. Dental calculus is a mineralized form of dental plaque that preserves the DNA of the oral microbiota, allowing its exploration long after the host's death. While prevalent among mammals, dental calculus has mostly been studied in humans and other primates. Here, we expand the analyses to

oral microbiome of 32 species (the majority newly sequenced), representing a large part of mammalian phylogenetic, dietary, and ecological diversity (including marine, semi-aquatic, and terrestrial species). We find that both host diet and higher-level host taxonomy (at the order level) affect what taxa are found in the oral microbiome, but host diet also affects the gene content and metabolic potential of these communities. A more fine-grained analysis (comparing the phylogeny of host species to that of individual microbial genomes) reveals only a moderate co-diversification signal for certain studied microbial clades. We therefore propose that the oral microbiome community is shaped primarily by the environmental conditions experienced by the host (as those are formed by host diet and genetic factors) and to a lesser extent by co-diversification due to vertical transmission.

What maintains the diversity of the gut microbiome in termite populations?

Dedeine F¹, Hervé V^{1,2}, Michaud C¹, Dupont S¹, Marie-orleach L¹

¹Institut de Recherche sur la Biologie de l'Insecte, UMR 7261, CNRS - Université de Tours, ²INRAE, AgroParisTech, UMR SayFood - Université Paris-Saclay

POSTER SESSION 1 - P01.098, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

For the microbiome to drive host adaptation, it is essential that the variation in host phenotypes mediated by the microbiome is heritable. Vertical transmission - the transfer of microbes from parent to offspring - is probably the most straightforward way to ensure such heritability in populations. However, vertical transmission is often imperfect, meaning that offspring possess only a subset of the parental microbial taxa. Nevertheless, many factors can maintain microbiome diversity across host generations, including natural selection, horizontal transmission, and host population structure and mating system. Despite their importance, these factors are difficult to study in field host populations and remain poorly understood.

We aim to understand how the diversity of gut microbial community of termites is maintained in populations. Termites are social insects that live in colonies, typically consisting of a royal couple (a queen and a king) and its offspring. The termite hindgut harbours a diverse community that enables digestion of dead plant material such as wood. Termite colonies are founded by a couple of winged reproductives called 'alates', which differentiate and fly away from two unrelated parental colonies. Alates play a crucial role in vertical transmission by harbouring gut microbes from their parental colony and passing them on to their offspring. Interestingly, because colony foundation requires both a queen and a king, termites may be one of the few species in which symbionts are transmitted by both parents (biparental transmission).

We recently analysed the gut microbial community in two populations of the termite *Reticulitermes grassei*. By sequencing amplicons of 18S and 16S rRNA genes, we characterised the community diversity within 24 colonies and estimated the vertical transmission rate of each microbial taxa by examining the gut

community of 336 swarming alates of both sexes.

Overall, the results show that vertical transmission of microbial taxa is imperfect; many alates harboured only a subset of the microbial taxa present in their parent colony. We then used simulation models to investigate factors that might compensate for the loss of diversity caused by imperfect vertical transmission. First, we tested the effect of an unbiased biparental transmission on community diversity within colonies. As new colonies are founded by two alates swarming from different parental colonies, they could receive different and complementary microbial taxa from their parents, potentially increasing diversity. Our simulation models using the alate data show that biparental transmission alone is not sufficient to predict the observed within-colony diversity in populations. We then tested three additional hypotheses. The first, called 'disassortative mating system', suggests that alate males and females with dissimilar and complementary gut communities mate more frequently than would be expected from random mating in populations. The second hypothesis, called 'colony level selection', suggests that incipient colonies with too low levels of community diversity die out rapidly in the population and are counterselected. The third hypothesis, called 'mixed-mode transmission', considers that termite colonies acquire symbionts not only from the couple of alates but also from the environment (horizontal transmission). For each model, parameter values that allow for the maintenance of community diversity in the population, and their relevance in the light of termite population biology will be discussed.

A bloody old habit: Conservation of gut-associated bacteria across blood-feeding leeches

Manzano Marín A¹, Trontelj P²

¹University of Vienna, ²University of Ljubljana

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Leeches (Euhirudinea) are a clade of segmented worms (Annelida) that groups well over 800 known species. Haematophagy, or blood feeding, is an evolutionary innovation that lies at their evolutionary origin: Leeches likely evolved by a shift in feeding habit of their ancestor from a freshwater ectocommensal to a bloodsucking fish parasite. Present-day leech species are either specialised on feeding on vertebrate blood or have secondarily become predators. An exclusive blood diet poses challenges such as facing a B-vitamin deficiency plus an accumulation of iron and urea, resulting from haemolysis and protein catabolism. However, leeches are themselves hosts to symbiotic microorganisms that can help the leech compensate these challenges. For example, while anticoagulant proteins are encoded in the leech genome, B-vitamin supplementation is carried out by well-described endosymbiotic bacteria. Previous studies have shown that core microbes associated to the digestive system (which are body-site specific) of two so-called medicinal leeches belong to the same higher taxonomic groups. Therefore, in this study we asked whether the associated microbes

of distantly related haematophagous leeches are conserved in terms of not only taxonomy, but potential metabolic functions. For this purpose, we have produced high-quality reference genomes as well as retrieved high-quality sequencing data from a number of leech species. Using this strategy, we reconstructed closed and lowly fragmented genomes for most recognised core-microbes of leeches. We found that a fraction of these symbionts show clear signs of genome reduction, suggesting a long history of vertical transmission. Moreover, these symbionts are closely related and often monophyletic, suggesting a long history of association with leeches. Finally, through genome-based metabolic inference, we identified conserved metabolic pathways in the symbiont genomes that may play an essential role in maintaining an haematophagous lifestyle. In summary, we produced the first genome-resolved catalogue of leech-associated bacteria, and through an integrative analysis, propose a likely ancestral role of the leech's core microbiota in not only the maintenance of a blood-based diet, but also in the evolution of their blood-feeding habit.

Are the root microbiome and plant phenotypic traits affected when a wild perennial is transplanted across contrasting habitats?

Lankinen Å¹, Aleklett K^{1,2}, Karlsson Green K¹, De Pasqual C¹, Andersen C¹, Ramirez Carrera N¹, Grenville-Briggs L¹

¹Swedish University of Agricultural Sciences, ²Lund University

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

Knowledge of how plant microbiomes are shaped and how the microbiota interact with their hosts are mostly based on studies from a few model species or crops. Less is known for wild non-model species, in particular how the microbiome could be interlinked with plant phenotypic plasticity across habitats. We have previously found that the root microbiota of the perennial vine *Solanum dulcamara*, a wild relative to potato with extreme phenotypic plasticity, differ among habitats ranging from dry beaches to wet forests but still possesses a similar core set of bacterial and fungi taxa. Here our overall aim was to understand how the root microbiome and plant phenotypic traits were affected by transplanting *S. dulcamara* from the three contrasting habitats beach, forest

and rural to a joint site. Using amplicon sequencing, we characterized root communities of bacteria and fungi in the natural populations and at the transplant site. We also studied phenotypic plant traits. We found that transplanted plants became very similar at the joint site compared to growing in their natural population in terms of growth, reproduction and nutrient status. The microbiota also become more similar, in particular the fungal communities, while the bacterial communities still showed some differences. While our results confirm that *S. dulcamara* is highly plastic and can easily adapt its growth to contrasting environments, it appears that the change in the microbial communities could be slower than that seen for phenotypic plant traits.

Bat gut microbiomes recapitulate host phylogeny and foraging niches

Melville D¹, Brändel S^{1,2,3}, Nolzen A¹, Kümmerle C¹, Geiger S¹, Wilhelm K¹, Tschapka M^{1,3}, Page R³, Wasimuddin W^{4,5}, Sommer S¹

¹Institute of Evolutionary Ecology and Conservation Genomics, Ulm University, ²Botanical Garden, Ulm University, ³Smithsonian Tropical Research Institute., ⁴CSIR-Centre for Cellular and Molecular Biology, ⁵Department of Animal Health and Food Safety, Norwegian Veterinary Institute

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

The role gut microbiota play in bat ecology and evolution remains a feverishly debated topic. Rapid gut transit times, low bacterial loads and weak signals of phylosymbiosis argue for a limited functional contribution, but the readiness with which bat gut microbial communities are affected by changes in diet, infections, or habitat disturbance paints a different picture. Here we re-examine evidence of phylosymbiosis and host specificity as well as the synchronicity of host foraging and microbiome changes in the so far largest collection of gut microbiomes (16S-rRNA taxonomic and PICRUSt2 inferred functional data; n=1211) from 16 bat species sampled along the Soberanía National Park in Panama. We detect clear signs of phylosymbiosis, which are strongly linked to diversification along foraging niches of phyllostomid bats. Evidence for co-

speciation was accompanied by moderate levels of co-diversification within foraging guilds sharing core ASVs, and taxonomic as well as functional specificity was highest for closely related hosts with shared foraging niche. Finally, we compared samples collected early in the night to those gathered later within the two bat species with the largest sample sizes to assess whether functionally relevant ASVs underwent temporal shifts from a starved to fed microbiome as evidence for co-synchronised biological rhythms of host and its microbiota. A shift was detectable and driven mainly by ASVs supporting host metabolic functions. Our work proposes that the evolved cross-talk between bats and the gut microbial symbionts is likely tied in with their diet specialisation and evolutionary diversification.

Behavioural Manipulation by Parasitic Nematodes is Associated with Microbiome Composition

Salloum P¹, Grupp J¹, Poulin R¹

¹University of Otago

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

Helminth parasites have complex life cycles, often going through a combination of free-living and parasitic stages in different hosts and habitats to achieve maturity and reproduction. Therefore, each helminth life stage has complex adaptations that enable them to reach the host or habitat required by their next stage. One of these adaptations is the remarkable ability of some helminths to induce water-seeking behaviour in their invertebrate hosts. For example, the adult mermithid nematode *Thaumamermis zealandica* must emerge from its host in water-saturated sand in order to reproduce. Previous work has shown that these parasites may induce their sandhopper hosts to bury deeper towards wet sand when compared to uninfected sandhoppers. However, there is variation in the level of behavioural change induced by conspecific parasites in their hosts, and variations in the microbiome have been proposed as a potential explanation for differences in behavioural manipulation, representing a form of microbiome-mediated plasticity.

We conducted an experimental test of the effect of the microbiome of *T. zealandica* parasites and of their sandhopper hosts on the degree of host behavioural alteration in a humidity gradient.

Sandhoppers were placed in tubes filled with vertical layers of wet sand at the bottom, humid sand in the middle, and drier sand on top. They were left under natural light and temperature overnight, following which they were trapped within the sections in which they were buried. Upon dissection, any infecting parasites, as well as haemolymph of infected and uninfected sandhoppers

were taken for microbiome characterisation with the V4 region of the 16S rRNA gene. In addition, all sandhoppers and worms were measured to account for potential effects of size (as a proxy for maturity) on microbial community composition.

The composition of the parasites' microbiota was significantly correlated with the depth at which their sandhopper host was found, regardless of the size of parasites and sandhoppers. Interestingly, no difference was observed between the sandhoppers' microbiota at different depths or between infected and uninfected sandhoppers. The microbiota of parasites, sandhoppers and of the surrounding sand was significantly different, with many microbial taxa found in parasites not detected in the sandhoppers or the sand, supporting that mermithid parasites have a microbiome of their own. The finding that the parasites' microbiota, and not the hosts', is associated with host burying depth supports the hypothesis that parasites' microbiomes may indeed play a role in the parasites' ability to manipulate their hosts' behaviour.

Evolutionarily, *T. zealandica* parasites that manipulate the behaviour of their hosts may have a fitness advantage over their non-manipulative conspecifics, since they are able to emerge in a suitable environment for reproduction (wet sand). Our finding that manipulative parasites have a different microbiome from non-manipulative parasites suggests that at least some components of the parasites' microbiomes may play a role in parasite-host interactions.

Beyond Genes: Modeling Microbiome-Mediated Responses to Selection

Week B^{1,2}

¹Zoological Institute, Kiel University, ²Max Planck Institute for Evolutionary Biology

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Microbiomes can shape host traits and fitness, yet we still lack a general framework for predicting when such microbial effects influence host evolution. In this talk, I present an extension of theoretical quantitative genetics that incorporates microbes—alongside host alleles—as contributors to trait variation, and propose to decompose microbiomes by sources of acquisition. Building on this decomposition, I introduce microbial analogues of additive genetic variance and narrow- and broad-sense heritability, and show how transmission mode governs whether microbial effects translate into a response to

selection. Using simulation models, I demonstrate that microbes acquired non-vertically can still mediate host adaptation if their acquisition is shaped by selection. These results suggest that standard approaches in microbiome-wide association studies may yield biased estimates of evolutionary relevance unless microbial transmission is considered. This framework not only generalizes core tools in quantitative genetics, but also offers a practical foundation for identifying which microbiome components matter for predicting trait change across generations.

Can the gut microbiome mediate long-lasting effects of early-life environmental conditions on adult thermal physiology?

Davies C¹, Furic C², Fleitz J², Palttala J¹, Reichert S², Ruuskanen S¹

¹University Of Jyväskylä, ²University of Turku

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

The ability to cope with temperature variation is a key challenge for all organisms. Individuals need to be able to quickly respond and adapt to increasingly unpredictable environmental variation across their lifespan. One promising mechanism that enables the host to adapt quickly to rapid environmental perturbations is the gut microbiome (GM). We recently showed in birds how short-term variation in environmental temperature alters the adult GM, this change having causal effects on host thermoregulatory performance. Thus, the GM can act as a source for phenotypic plasticity. In addition to this, the host-associated GM has further been suggested to help mediate developmental plasticity, but data from wild populations is scarce. Therefore, to explore whether the GM can act as a mediator for host developmental plasticity we studied the long-lasting effects of the early-life environment on adult thermal physiology using wild great tits (*Parus major*)

as the study system. During the main growth period, wild nestlings were either unmanipulated to serve as control individuals, exposed to altered temperatures to establish the effects of early-life thermal environment, or administered antibiotics to directly modify GM, and test whether the GM is mediating effects on host thermal physiology. First, growth and survival until fledgling was monitored in all individuals (n=528). Second, a subset of individuals (n=114) were reared in outdoor aviaries until adulthood in late winter, and various metabolic and thermal traits (including whole animal metabolic rate, cold tolerance, and mitochondria function) were measured. By conducting manipulative experiments in the wild, combined with common rearing under similar conditions this study can shed light on the role the GM can play in mediating the effects of early-life thermal environment on thermoregulation into adulthood.

Elucidating interactions of the microbiome and host genomics during population decline through a temporal hologenomics approach

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

Population decline is exacerbated by a myriad of factors, including habitat degradation, climate change, competition and predation from invasive species, and loss of genetic diversity. Genomic depauperation is of particular concern, as low diversity and inbreeding not only affects population fitness and disease susceptibility, but may also impact a species' capacity to adapt to novel or changing environments. While the importance of genetic diversity has been recognised for several decades, we are only just beginning to gain insight into the crucial roles that microorganisms play in species conservation. Symbiotic microbiomes play a central role in many biological processes and are intrinsically linked to host health. The composition of host-associated microbiomes is mediated by host genetics, which is particularly relevant to wild systems in the face of global climate change and rapid population declines. It is thus crucial to understand how changes in genetic diversity impact host-microbiome interactions. Achieving this goal in wild populations requires samples that span decades-centuries of population declines, yet host

associated microbiomes often do not preserve after host death. To address this significant knowledge gap, we utilise dental calculus, the calcified oral microbiome, from museum-preserved specimens of Scandinavian brown bears that experienced a dramatic population bottleneck over the course of the last 200 years. We observed the prevalence of oral disease increased over time, even after population recovery ($p < 0.001$). We then characterised the temporal diversity and function of oral microbiomes in healthy and diseased brown bears to define dysbiotic profiles directly associated with caries and diseased individuals. Moreover, we also explored the influence of a disease phenotype on microbial communities sampled from non-affected teeth to characterise spatial microbiome variation in diseased bears. Understanding the interplay between symbiotic microbial communities and host genetic diversity, i.e. hologenomics, is necessary for predicting the impact of host population decline from a holistic perspective, encompassing the consequences of altered microbiome composition and function on overall host health.

Functional implications of changes in the rumen microbiome

Leonard A¹, Fohringer C, Martin Schmidt N

¹Aarhus University

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

The arctic climate is changing faster than anywhere else on the planet, most notably in terms of warming. For arctic herbivores such as muskox (*Ovibos moschatus*), climate change also means changes in the quality of their diet. As the Arctic continues to warm, plant nitrogen is expected to decline by as much as 14% in the key foraging areas of arctic herbivores. Genetic variability of the muskox is low due to multiple population bottlenecks over time, and populations may be poorly equipped to deal adapt to rapid environmental change. The extent to which the rumen and gut microbiome may either buffer or exacerbate the effects of such climate-induced declines in plant diet quality is currently unknown.

We used a controlled, longitudinal experiment on a captive muskox herd manipulating diet quality with repeated sampling over a 12-week period to understand the functional implications of rumen microbiome changes for ungulate energy acquisition. We combined metabarcoding, metabolomics, and lab-based digestion experiments to assess

rumen microbiome function. Based on well-understood metabolic pathways, quantification of the metabolome allows for the evaluation of the function of the metabolism while digestion capacity provides a direct measure of rumen microbial function.

We observed rapid microbial responses, with changes in diversity patterns being reflected in the metabolic concentrations. We show that declining forage quality increased microbiome diversity, leading to a wider range of metabolic capabilities within the gut and increased digestive capacity. This suggests a strong functional link between the gut microbial community structure and the metabolic landscape enabling hosts to buffer forage quality declines and maintain adaptive capacity. By linking microbiome composition and function, we elucidate the rumen microbiome's role in the adaptation of high-latitude ungulates to rapid environmental change, a crucial factor for predicting their future viability in a warming Arctic.

How the environment, genome, and microbiome influence niche width in spider mites

Bisschop K^{1,2,3}, Uller T³, Feiner N^{3,4}, Zélé F⁵, Wybouw N², Bonte D², Decaestecker E¹

¹KU Leuven Kortrijk, ²Ghent University, ³Lund University, ⁴MPI Plön, ⁵University of Montpellier

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

Adaptation to global change depends not only on genetic adaptation and phenotypic plasticity, but also on host-associated microbiota, which may influence nutrient uptake and detoxification, ultimately enhancing host resilience and expanding ecological niches. What drives some individuals to specialise while others remain generalists? To explore this, we studied the two-spotted spider mite (*Tetranychus urticae*), a herbivore with a host range

spanning over 1000 plant species. Combining field sampling in Southern France with lab experiments on isofemale lines, we measured performance across five host plants to identify niche width, and used whole-genome resequencing to uncover genetic and microbial contributions to niche variation. This work sheds light on the interplay of environment, genetics, and microbiomes in shaping adaptive potential and niche width.

Influence of Gut Microbiota Perturbation on Obligate Endosymbiont Abundance and Host Phenotype in the German Cockroach (*Blattella germanica*)

Ray S^{1,2}, McMahon D^{1,2}

¹Freie Universität Berlin, ²Bundesanstalt für Materialforschung und -prüfung (BAM)

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

The German cockroach (*Blattella germanica*) maintains a dual symbiotic system comprising the obligate intracellular endosymbiont *Blattabacterium*—housed within specialised bacteriocytes proximal to the urocytes—and a complex gut microbiota. While *Blattabacterium* is integral to host nitrogen metabolism, including uric acid degradation and essential nutrient biosynthesis, the extent to which its abundance and function are influenced by the surrounding gut microbial community remains insufficiently characterised. In this study, we investigated how experimental manipulation of the gut microbiota impacts *Blattabacterium* abundance and host phenotype. Our study aims to offer new insights into the multi-level host-microbiota interactions of this important hemimetabolous pest insect species. Experimental cohorts included a conventionally reared group (NS), alongside four sterile or semi-sterile treatment groups: (i) sustained antibiotic exposure post-sterilisation (AB), (ii) two-week antibiotic regimen (AS), (iii) two-week antibiotic

treatment followed by re-inoculation with a conventional gut suspension (GS), and (iv) re-inoculation with both gut suspension and faeces (GSf). Quantitative PCR (qPCR) was used to assess *Blattabacterium* abundance, while 16S rDNA amplicon sequencing enabled characterisation of gut microbiota diversity and taxonomic shifts across treatments. Phenotypic parameters, including developmental progression and expression of immune-related and metabolic genes, were assessed via transcriptomic profiling. Moreover, host resilience to pathogenic challenge was evaluated through survival assays following infection with Rifampicin-resistant *Pseudomonas entomophila*. This is to understand whether microbiota disruption influences host immunity. Collectively, our findings provide novel insights into the dynamic, multi-tiered interactions between host, endosymbiont, and microbiota, with implications for understanding microbial modulation of host physiology in hemimetabolous insect systems.

Microbiome structure of French Guyana *Drosophila* community

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Biological invasions threaten ecosystems worldwide, yet the multifaceted role of microbial communities in facilitating invasion success remains poorly understood. While theory suggests that microbiomes may be key players in invasion dynamics, empirical evidence from natural systems has been scarce. Leveraging the coexistence of native and invasive *Drosophila* species in the neotropics of French Guiana, we dissected their microbiome profiles across an anthropogenic gradient by revealing structuring patterns consistent with microbial acquisition and adaptation theories.

Using multi-marker amplicon sequencing (16S, ITS, EF1), we uncovered distinct microbiome signatures between invasive and native hosts, with native species harboring significantly higher microbial diversity. Intriguingly, 326 of the 327 microbial OTUs in invasive species were subsets of those found in most native hosts. While native *Drosophila* shared a core set of dominant microbes, invasive conspecifics displayed host-specific microbiome restructuring, each carving out a unique microbial niche. In natural ecosystems, invasive alien species come into contact with resident species and their associated environments, likely by acquiring the

microorganisms from local microbial communities. These interactions may contribute to the observation that the microbiome of invasive alien species often resembles a subset of the native species' microbiome. Within this context, Baas-Becking's conjecture that "everything is everywhere, but the environment selects" may help explain the differences in microbiome composition of invasive alien species upon their arrival and acclimatization. According to this framework, invasive *Drosophila* species — acting as environments for their own microbiomes — could differentially select microorganisms from resident species based on ecological or physiological affinity.

Our findings support a theoretical dynamic picture: invasion is not just about the alien invader species itself but also driven by microbiome-level negotiations. The selective acquisition and reorganization of native microbes could equip invasive species with context-dependent advantages, potentially easing their establishment. Our work supports the current shift in paradigm from host-centric invasion biology to a more holobiont perspective, where microbiome plasticity could be a hidden catalyst for invasion success.

Of mice and microbes: the gut microbiome as a driver of thermal plasticity.

Wagener C¹, Coombes H¹, Figueiredo A¹, Lu R¹, Pearson C¹, Sanchez N¹, Wanelik K¹, Hanski E¹, Knowles S¹

¹Oxford University

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Phenotypic plasticity enables animals to rapidly respond to changing environments, and recent advances suggest the gut microbiome could be a critical, but underexplored, avenue for such plasticity. While studies with laboratory mice (*Mus musculus*) have revealed the gut microbiome's influence on host physiology, these lack the microbial diversity and ecological context of natural populations. In wild populations, evidence linking the gut microbiome to host phenotypes is largely correlational. This leaves critical questions of how relevant laboratory insights are for wild systems, and the significance of microbiome-mediated host plasticity in nature.

To address this gap, we studied an insular population of wild house mice. We combined extensive characterisation of their gut microbiota and phenotypic variation with faecal microbial transplant experiments to test whether natural, within-population variation in the gut microbiome casually influenced phenotypic traits. In a five-year dataset (of 1665 samples from 745 individually marked mice), we first identify host and environmental drivers of gut microbiome variation. Next, using a subset of the dataset we focus on thermoregulatory

phenotypes, and ask how they are predicted by host and environmental factors, including gut microbiota composition. Finally, we conducted faecal microbial transplant experiments into germ-free mice to test whether the thermal phenotypes of wild mice are transferable with their microbiota. Our data reveal striking seasonal variation in both the microbiota and thermal phenotypes of house mice. Mice sampled in spring exhibited a 1.5°C lower body temperature than those sampled in summer and autumn. Remarkably, these seasonal differences in body temperature were transferable to gnotobiotic mice via faecal microbiota transplants. Spring microbiome transplants induced a 2.0°C lower body temperature than summer or autumn microbiome transplants. We further find a strong correlation between donor and recipient body temperature. Other traits of recipient mice also differed according to which season the microbiome donor was sampled in.

These results provide some of the first evidence that within-population (seasonal) variation in the gut microbiome mediates host physiological plasticity, underscoring its role as a critical factor shaping natural phenotypic variation and potential acclimation capacity of wild mammals.

Proteomic Profiling Reveals Brain Proteins Linked to Social Interactions in Gut Microbiota-Harbouring Honeybees

Calderoni G¹, Wu Y¹, Holtzmann M¹, Perruchoud C¹, Liberti J¹

¹University Of Geneva

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

What factors regulate social behaviour has long been a key question in biology, yet its molecular determinants remain poorly understood. Social behaviour is known to be influenced by both internal physiological states and external social cues, with the gut microbiome emerging as a key internal stimulus that promotes social behaviours across various animal models. Honeybees provide a powerful model for investigating the molecular mechanisms connecting gut microbes to host social behaviours and the emergent properties of group living, as their microbiota is manipulable and their individual and group behaviours can be precisely quantified. Previous research has shown that honeybees possessing a gut microbiome exhibit more frequent and specialized social interactions compared to

gut microbiota-depleted bees. To shed light on the molecular mechanisms underlying these interactions, we performed a proteomic analysis after dissecting the brain of gnotobiotic bees into three regions: optic lobes, mushroom bodies, and antennal lobes. We found large region-specific effects of the gut microbiome on the brain proteome. We then correlated protein abundance with social behavioural data, identifying candidate proteins which may be responsible for the observed behavioural differences between microbiota-colonised and microbiota-depleted bees. Our results suggest that brain region-specific changes in protein abundance are key mediators of the interaction between the gut microbiome and honeybee social brain.

The effects of climate change on the microbial community associated with a butterfly across a 30-year period

Sun L¹, van Dis N¹, Saastamoinen M¹, Ekroos J¹, Duploux A¹

¹University Of Helsinki

MEETING ROOM 116, August 18, 2025, 10:30 AM - 12:30 PM

Microbial communities in host guts are essential for host fitness yet highly sensitive to environmental fluctuations such as temperature shifts. While short-term responses—like the rapid proliferation of thermotolerant bacteria after a heatwave—are well documented. However, the long-term and indirect consequences of sustained warming on these communities remain poorly understood. In this study, we analyze three decades of microbiome data from diapausing larvae of the Glanville fritillary butterfly (*Melitaea cinxia*) in the Åland Islands, Baltic Sea, to test two hypotheses: a) Sustained warming in Åland has selectively promoted or suppressed some bacteria, thereby restructuring the larval gut community over time. b) The

functional repertoire of key bacterial assemblages has evolved to help the host withstand higher temperatures—through enhanced production of protective metabolites, heat-shock proteins, or other temperature-mitigating mechanisms. To evaluate these hypotheses, we combine 16S rRNA amplicon sequencing with long-term climate record to characterize temporal changes in community structure. And use shotgun metagenomics data to reconstruct functional gene profiles of the major bacterial community. By disentangling how warming shapes not only who is present but also what they can do, this work will shed light on the resilience and adaptive capacity of host–microbiome partnerships under ongoing climate change.

The gut microbiome of invasive squirrels shows greater diversity, stability and functional potential than that of their native competitors

Romeo C^{1,2}, Gaun N¹, Tranquillo C³, Wauters L³, Alberdi A¹

¹University of Copenhagen, ²Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna, ³University of Insubria

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Background: Due to their influence on key host phenotypic traits and their capacity for rapid genomic and compositional shifts, highly diverse and/or plastic host-associated microbiomes may play a role in mediating animal invasions, facilitating the establishment and spread of alien species, and enhancing their competitive advantage over native species. To explore this, we analysed the gut microbial communities of invasive grey squirrels (*Sciurus carolinensis*) and outcompeted native red squirrels (*Sciurus vulgaris*) in Italy, comparing their overall composition and their plasticity in response to environmental variation.

Materials and methods: The two squirrel species were live-trapped across urbanisation gradients and seasons in multiple study areas in NW Italy, resulting in the collection of 110 and 80 faecal samples from 63 native and 45 invasive squirrel individuals, respectively. Following the standardised protocols of the Earth Hologenome Initiative (www.earthhologenome.org), we conducted shotgun metagenomic sequencing to enable genome-resolved metagenomic analyses. After assembling metagenomic reads, we reconstructed metagenome-assembled genomes (MAGs), annotated them taxonomically and functionally, and quantified their relative proportion across all samples.

Results: The metagenomic analysis resulted in 1,687 MAGs from 13 different phyla, of which 82% had no species-level annotation. The 30% of MAGs were common to both species, 29% were exclusive to native red squirrels and 41% were exclusive to invasive grey squirrels. Alpha diversity metrics were consistently higher in invasive squirrels, and the microbial communities of the two species differed significantly in structure and composition. Overall, the microbiota of native squirrels was enriched in lactic acid bacteria (fam. Bifidobacteriaceae, Streptococcaceae and Lactobacillaceae), which were absent or almost absent in invasive

individuals. The invasive host microbiota was instead enriched in Verrucomicrobiota and several Bacillota A families (e.g. Oscillospiraceae and Lachnospiraceae). While the microbiota of native squirrels were highly variable, with several samples also showing signs of dysbiosis, all invasive individuals harboured highly diverse and very consistent communities. Indeed, the relative abundance of most bacteria in native squirrels was strongly influenced by seasonality and to a lesser extent by urbanisation, resulting in significant shifts in microbiota structure over space and time. Most of these changes appear to be driven by a large increase in the abundance of lactic acid bacteria in winter and in urban areas. In contrast, the microbiota of invasive squirrels was compositionally more stable, with far fewer bacteria responding to change in any way. Despite this greater structural stability, the microbial community of invasive squirrels still showed a degree of functional variation similar to, if not greater than, that observed in native ones. The higher proportion of specialised bacteria observed in invasive squirrels may allow small changes in the abundance of a few taxa to result in large functional changes without altering community structure. Finally, dietary analysis confirmed that the two species have very different diets, with grey squirrels feeding mainly on oak acorns and red squirrels feeding mainly on conifer seeds. Indeed, the microbiome of grey squirrels was significantly enriched in tannase-producing bacteria, which are essential for degrading toxic acorn tannins.

Conclusions: The gut microbiome of invasive grey squirrels is more diverse, stable and functionally enriched than that of outcompeted native red squirrels, with a capacity for large functional variation without compromising community structure. These features suggest that microbiome-mediated plasticity may play a key role in the ecological success and competitive advantage of the invasive species.

The role of the host-associated microbiome in host tolerance and cross-tolerance to pollutants

Van de Maele M¹, Janssens L¹, Decaestecker E¹, Stoks R¹

¹KU Leuven

MEETING ROOM 116, August 18, 2025, 2:00 PM - 5:00 PM

Populations frequently exposed to a pollutant can evolve tolerance to this pollutant. Tolerance to one pollutant can extend to other pollutants, so-called cross-tolerance. Understanding patterns of cross-tolerance is important as populations are increasingly exposed to multiple pollutants. While host mechanisms of (cross-)tolerance are well studied, and while it is known that the host's microbiome can contribute to tolerance of its host to pollutants by lowering the toxicity of pollutants for the host, it remains untested whether the host's microbiome may also play a role in driving cross-tolerance. In this study, we focused on the host-associated microbiome community as underlying mechanism of its host's tolerance and cross-tolerance.

We build on an experimental evolution trial during which *Daphnia magna* clones adapted and evolved tolerance towards the pesticide chlorpyrifos, which resulted in cross-tolerance to the pesticides malathion and carbaryl, while not affecting tolerance to the pesticide esfenvalerate and reducing tolerance to the pesticide imidacloprid and the pharmaceutical fluoxetine (as a cost of tolerance). We determined whole body microbiome community compositions (using 16S rRNA amplicon sequencing) of two chlorpyrifos-sensitive and two chlorpyrifos-tolerant clones after four-days exposures to a control or to sublethal pollutant concentrations of chlorpyrifos, malathion, carbaryl, esfenvalerate, imidacloprid and fluoxetine.

Under control conditions, chlorpyrifos-tolerant clones had a different bacterial community composition than chlorpyrifos-sensitive clones, suggesting that microbiome shifts contributed to their evolution of tolerance to chlorpyrifos. Exposure to the organophosphates chlorpyrifos and malathion did not change the bacterial community composition of the chlorpyrifos-tolerant clones compared to the control, whereas chlorpyrifos-sensitive clones did show compositional changes. This suggests that the microbiome of chlorpyrifos-tolerant clones is adapted to organophosphates and includes bacteria (e.g.

Pseudomonas, *Enterobacter*) which may possess organophosphate-degrading enzymes. These bacteria may contribute to the host's tolerance to chlorpyrifos and cross-tolerance to malathion.

Although there is cross-tolerance among chlorpyrifos and the carbamate carbaryl at the host level, this was not observed at the microbiome level as exposure of the chlorpyrifos-tolerant clones to carbaryl shifted their bacterial community composition towards that of the sensitive clones exposed to carbaryl. This suggests that bacteria mediating tolerance to chlorpyrifos cannot degrade carbaryl (because of their different molecular structure). Also for imidacloprid, the bacterial community composition of chlorpyrifos-tolerant clones shifted towards the composition of chlorpyrifos-sensitive clones upon exposure, indicating no cross-tolerance at the microbiome level. For esfenvalerate and fluoxetine, no microbiome changes were observed in either tolerance type.

Our results show that host-associated microbiome responses to pollutants are pollutant-specific and depend on host tolerance type, consistent with the idea that evolution of tolerance in the host is associated with changes towards a microbiome that is capable to degrade specific types of pollutants. The evolution of chlorpyrifos tolerance in *Daphnia* was associated with microbiome shifts contributing to both tolerance to chlorpyrifos and cross-tolerance to malathion. However, this microbiome-mediated tolerance was not observed for carbaryl, highlighting that microbial and host mechanisms of cross-tolerance are complementary. Microbiome-mediated cross-tolerance appears to depend on the pollutant's chemical structures, while host-level cross-tolerance is related to pollutant's shared modes of action and detoxification pathways. This study provides the first experimental indication that host-associated microbiomes influence not only the host's tolerance but also its cross-tolerance to pollutants, underscoring the microbiome's potential in host adaptation to pollutants

Evolutionary Adaptation to Juvenile Malnutrition and Investment in Sexual Conflict

Canal Domenech B¹, Kawecki T¹

¹University Of Lausanne

POSTER SESSION 3 - P03.157, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

In many species, including *Drosophila*, males allocate resources to costly sexual traits that mediate competition for female gametes and often result in sexual conflict. Under chronic nutrient limitation, selection may be predicted to favor reduced investment in these traits because their energy and resource costs are likely to have a greater impact on survival of nutritionally stressed individuals. On the other hand, exposure to nutrient shortage over multiple generations should promote physiological adaptation to nutrient shortage, leading to a more efficient resource use, which would leave more resources available to be invested in sexual traits.

We test these contrasting predictions about how long-term adaptation to malnutrition influences the evolution of male

reproductive traits, using experimental evolution in *Drosophila melanogaster*. We compare 'selected' males from replicate populations that evolved on a nutrient-poor larval diet for over 300 generations to 'control' males evolved on a standard diet, testing each on both poor and standard diets, which allows us to study both the evolutionary responses and phenotypic plasticity. We focus on traits mediating postcopulatory components of sexual selection and conflict, including success in sperm competition and the ability to inhibit female remating, as well as the underlying investment in seminal fluid proteins, a key factor in male competitive reproductive success. Our results throw light on how an interaction between nutritional conditions and metabolic adaptation shapes sexual conflict.

Fecundity help may be more common than survival help in realistic ecological scenarios

Bolton M¹, Early R¹, Kuijper B¹

¹University Of Exeter

POSTER SESSION 3 - **P03.150**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The evolution of social behaviours - such as altruism - strongly depends on an organism's lifecycle. Existing theoretical predictions on the evolution of altruism typically consider life histories in which population turnover is driven by adult mortality in response to external factors (death-birth), or life histories in which births drive population turnover by triggering adult deaths (birth-death). The first of these - death-birth- is a simplification of species lifecycles in which adults must die before juveniles have a chance to establish as breeders. Conversely, birth-death can be thought of as representing species where juveniles put survival pressure on adults. Which mechanism is chosen has profound consequences for the evolution of help.

However, death-birth and birth-death sit at two extremes. Therefore, we aim to represent a more natural scenario by developing two hybrid update mechanisms. These occupy a middle ground in which

population turnover is driven both by external effects on mortality, and intergenerational competition for survival triggered by the birth of juveniles. We use two slightly different mechanisms; one in which all adults and juveniles compete for survival in the same pool (full scramble), and the second in which individual adults compete independently against subsets of juveniles (adult defence). In both, altruism is only able to evolve when help affects fecundity, not when it affects survival. From this finding, we suggest natural populations may be more likely to exhibit fecundity-based help. Survival-based altruism may only arise in the presence of additional population characteristics which increase the evolutionary scope for help. Additionally, because generational overlap promotes the evolution of help, we suggest that survival-based feedback loops may arise when help affects the rate of population turnover.

Reciprocal influence on viral load and effects on virulence in co-infections with latent ALSV and phylogenetically distinct viruses

Lafforgue G¹, Metais A

¹INRAE

POSTER SESSION 3 - **P03.179**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Plant virus co-infections are ubiquitous and can dramatically alter disease outcomes. Understanding the interactions between different plant viruses is crucial for managing viral diseases and ensuring global food security. This study focuses on Apple latent spherical virus (ALSV), a bipartite virus known for its broad, asymptomatic host range, and its influence on a diverse set of co-infecting viruses. Utilizing *Nicotiana benthamiana* as a model host, we investigate the impact of ALSV co-infection on viruses belonging to the Bromoviridae, Virgaviridae, Alphaflexiviridae, Potyviridae, Secoviridae and Caulimoviridae families.

We hypothesize that ALSV, despite its latent nature, may significantly influence the dynamics of co-infecting viruses and vice versa. To test this, we quantified individual viral loads in both mono- and co-infection scenarios, focusing on two key aspects:

1. Impact on Viral Accumulation: Does the presence of ALSV enhance, reduce, or have no effect on the accumulation of other viruses?
2. Genomic Formula Stability in Multipartite Viruses: any of the viruses in this study,

including ALSV, have multipartite genomes. Does co-infection alter the RNA ratios of these viruses, potentially impacting their replication and functionality?

Furthermore, we assessed virulence through plant growth measurements to determine the nature of the virus-virus interactions (neutral, antagonistic, synergistic). By exploring these facets of co-infection, we aim to shed light on the complex interplay between ALSV and a diverse set of plant viruses, and ultimately determine if phylogenetic relationships influence interaction outcomes.

Our results revealed a range of interactions, including neutral, neutral-antagonistic, on viral load and synergistic effects for virulence in a particular case. Interestingly, the genomic formula of some multipartite viruses may be modulated in co-infection situations. These findings highlight the complex nature of plant-virus interactions and emphasize the importance of understanding the implications of co-infections for plant health and disease management.

Keywords: plant viruses, co-infection, viral load, genomic organization, virulence

Sexual Selection and the Evolution of the Mammalian Brain and Social Cognition: A Proposal on the Evolution of Selfishness and the ‘Male Brain Meme’ Concept

Ito M¹

¹School of Science, Kitasato University

POSTER SESSION 3 - P03.159, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Our research group recently reported that selfish DNA contributes to the emergence of a novel sex-determining gene and to biased subgenome evolution following interspecific hybridization (1, 2). In the present study, I shift focus from the molecular level to the individual and population levels to explore the evolution of selfishness in mammals and humans.

Sexual size dimorphism in vertebrates varies widely across taxa. In amphibians, females are typically larger, whereas in fishes, reptiles, and birds, the patterns depend on ecological and phylogenetic contexts. However, in most mammals, males tend to be larger—a trend that can be explained by Darwin’s theory of sexual selection, particularly male–male competition. This presentation offers a novel perspective by examining the human social brain through the lens of evolutionary biology, focusing on mammalian evolution, brain sexual dimorphism, sex steroid hormones, social behavior, and the evolution of human society.

Nocturnality and Male–Male Competition: Mammalian ancestors are believed to have been nocturnal. This section explores the evolutionary linkage between nocturnality, visual gene adaptation, and sexual selection, and proposes the concept of the “mammalian Male Brain,” characterized by

increased aggression and combativeness. Harem structures exemplify polygyny driven by such traits. The mammalian male brain can thus be viewed as an expression of selfishness at the individual level.

Sex Steroid Hormones and the ‘Male Brain’: In most mammals, androgens shape the structure of the male brain during fetal development. I introduce the concept of the “Residual Male Brain,” referring to the persistence of aggression and violence even after androgen levels decline in adulthood.

Cooperative Aggression and Group-Level Selfishness: I analyze violent intergroup aggression in male groups of chimpanzees and humans, proposing that intragroup cooperation against outgroup males is a foundational mechanism of war. This cooperative aggression can be interpreted as a form of selfishness at the group level.

Proposal of the ‘Male Brain Meme’: I define the “Male Brain Meme” as a cultural construct based on evolutionarily derived male aggression. It supports dominance structures characterized by authority and power. I discuss its evolutionary implications and its role in sustaining male-dominated societies and warfare.

Studying the evolutionary impact of parental influence on mate choice in human societies

Awasthi K¹, Henshaw J

¹Albert-Ludwigs-Universität, Freiburg

POSTER SESSION 3 - P03.155, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Human parents exert significant influence over their children's choice of mating partners in many modern societies, reflecting a trend likely prevalent throughout our evolutionary history. This influence creates an evolutionary conflict between parents and their adult offspring, whose fitness interests may diverge regarding the latter's choice of partner. This is especially true if parents can continue to produce offspring directly, rather than investing in their (less genetically related) grandoffspring. Consequently, parents may

be expected to prioritise factors such as resource acquisition when choosing partners for their children, often mediated through practices like bride-prices and dowries. However, this directly conflicts with the offspring's aim to maximise their own fitness through partner selection. Through theoretical analysis and agent-based simulations, we explore this conflict's evolutionary implications, including its effects on mate-choice strategies and demographic trends.

Substrate hardness and social environment drive egg clustering behaviour in *Drosophila melanogaster*

Fowler E¹, Friend L¹, Churchill E², Yu D¹, Archetti M³, Bourke A¹, Bretman A³, Chapman T¹

¹University Of East Anglia, ²University of Leeds, ³Pennsylvania State University

POSTER SESSION 3 - P03.140, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Egg placement decisions can have profound fitness consequences. One oviposition strategy reported across taxa is laying eggs in clusters, including with eggs of conspecific individuals. However, the drivers of egg clustering behaviour remain poorly understood. Egg clustering could have significant fitness benefits, including the potential to share resources provided by a neighbouring egg (e.g. externally deposited microbes or defensive compounds). Additionally, offspring emerging from a cluster of eggs may cooperate or compete over access to nutrients and other resources. Using the fruitfly, *Drosophila melanogaster*, we tested: 1) whether females plastically adjust egg clustering based on substrate hardness; 2) whether social context influences egg placement on hard and soft substrates; and 3) which sensory inputs underlie egg clustering behaviour.

Females laid fewer eggs, but increased egg clustering, on harder substrates. Grouped females laid more eggs than isolated ones, but this difference was only found for hard substrates. Surgical manipulations of key sensory organs revealed that the antennae and labellum were essential for egg laying on hard substrates only, while females lacking foretarsi laid eggs on all substrates but no longer exhibited egg clustering plasticity. The results revealed that egg clustering behaviour is plastic according to substrate condition, and that social cues interact with other environmental factors to influence oviposition decisions. Mechanosensory inputs via the tarsi are likely important for females to fine-tune egg positioning. This characterisation of egg clustering behaviour in *D. melanogaster* enables future investigation of the fitness consequences of fine-scale oviposition strategies.

The cooperation inside us: investigating bacterial cooperation in the human gut

Katz Z¹, Belcher L¹, Dewar A¹, West S¹

¹University Of Oxford

POSTER SESSION 3 - P03.162, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The bacteria in our gut are thought to play a major role in our development, behaviour and disease. Rather than acting in isolation, bacteria are extremely social. Cells secrete molecules which benefit nearby cells, with this cooperation allowing the invasion of hosts and acquisition of nutrients. However, the evolution of cooperation is not well understood in our gut communities. Particularly, it is unclear what kind of selection pressures influence cooperation in gut bacterial communities. To explore this, we analysed gut metagenome data from 231 humans. We calculated the species' relatedness (how similar strains are to one another), polymorphism and protein divergence of genes encoding for cooperative and private traits. We found that the number of cooperative genes varied greatly between species, but the proportion

of cooperative genes increases as species' relatedness increases. We then examined whether genetic diversity in these genes was correlated with the relatedness of species. Evolutionary theory suggests that genes for cooperation should be under relaxed selection, which should mean that diversity in genes for cooperative relative to private traits would increase as relatedness decreases. However, opposite to these predictions, we found that species with higher relatedness showed higher relative polymorphism in genes for cooperative compared to private traits. This suggests that other factors are at play. For example, selection on cooperation in the gut might be different compared to other systems studied so far. Further investigation and statistical analysis are under way to find out.

The socio-sexual environment influences diet and oviposition site choice in female fruit flies

Sydney M¹, Perry J², Chapman T¹

¹University of East Anglia, ²St. Francis Xavier University

POSTER SESSION 3 - **P03.146**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The balance of macronutrients that animals consume has key impacts on reproduction and lifespan, and individuals are able to actively regulate their macronutrient intake by feeding from diets of differing composition. The social and sexual environment can also be important drivers of diet choice behaviour. For example, male harassment pushes females away from high-quality foraging patches in some insects, while foraging in groups can result in collective feeding from a single patch. However, it is unknown how female insects balance a need to optimise macronutrient intake against cues of patch quality provided by conspecifics of the same and opposite sex and different risks of male harassment across food patches. In this study, we investigated female feeding choice in response to same-sex and opposite-sex social environments. Female feeding choice between two diet patches differing in macronutrient composition were measured in fruit flies (*Drosophila melanogaster*) in experimentally controlled socio-sexual

groups. We experimentally manipulated whether females could physically interact with non-focal individuals or could only perceive cues of non-focal individuals that were restricted behind barriers. Contrary to our predictions, females did not exhibit a preference for protein-rich diet patches, and macronutrient preference was not modified by harassment from unrestricted males. Interestingly, females did not avoid restricted males, despite a risk of harassment. Instead, females moved to the most populous patch, regardless of macronutrient content. These results suggest that females might have used the presence of males as a signal of foraging patch quality and prioritised social information above both direct information on nutrient quality and harassment risk. I will also discuss patterns of female feeding and oviposition when patches contain social cues of male versus female conspecifics, to further dissect the role of sex in social signals of foraging quality.

Ejaculate-driven trade-offs: increased fertilization success comes at the cost of lower offspring quality

Romero-Haro A¹, Mulder E², Verhulst S², **Tschirren B**³

¹National Museum Of Natural Sciences, ²Groningen Institute for Evolutionary Life Sciences, University of Groningen, ³Centre for Ecology and Conservation, University of Exeter

MEETING ROOM 131, August 21, 2025, 10:30 AM - 12:30 PM

Besides DNA, fathers can transfer non-genetic factors during copulation, which can affect offspring phenotype (i.e., ejaculate-mediated paternal effects; EMPEs). Today it remains unclear if EMPEs are adaptive, a selectively neutral side effect of copulatory interactions, or even detrimental for the offspring. The latter scenario could arise if ejaculate components that increase male fitness, for example through increased fertilisation success, have detrimental effects on individual offspring quality (quality – quantity trade-off), resulting in parent-offspring conflict. EMPEs have been studied mostly in invertebrate species, and their generalisation—or even their presence—in other taxa is poorly known.

Male quail of the genus *Coturnix* are unique among birds in that they produce a white foam, secreted by the proctodeal (or cloacal) gland independently of sperm and seminal fluid, which is transferred during copulation. This foam consists of viscous, aerated glycomucoproteins, which boosts fertilisation success and may influence sperm competition outcomes. Certain foam components have been shown to fuel sperm, enhancing its motility, velocity and longevity, with glucose and lactate identified as main

energy suppliers. However, the factors that shape heterogeneity in foam composition among males and the consequences of foam transfer for the offspring remain unknown. Here we tested whether foam components that improve male fertilisation success influence offspring quality at birth in Japanese quail (*Coturnix japonica*). To this end, we took repeated foam samples from males to quantify foam mass and concentrations of foam lactate and glucose and to assess trait repeatability. Then, males were mated with a randomly allocated female, and we quantified offspring body mass and blood telomere length (by TRF), a biomarker of physiological damage and ageing.

We found a high repeatability of all foam traits. While no association between foam components and offspring body mass was found, foam glucose concentrations were negatively associated with offspring telomere length at birth ($r = 0.58$). These findings highlight that non-genetic foam components transmitted during copulation affect offspring phenotype and that fathers and offspring are in conflict over copulatory foam composition in this precocial bird.

Larval Altruism and the Development of a Worker Caste - Theoretical Investigations into Primitively Eusocial Wasp Larvae as Altruists.

Thatcher D¹, Radford A¹, Kennedy P¹

¹University of Bristol

MEETING ROOM 131, August 21, 2025, 10:30 AM - 12:30 PM

For decades, both empirical and theoretical research on the eusocial insects has focussed on the role of adult altruism, but the possible importance of larvae as helpers has received surprisingly little attention. Larvae of social wasps (and some other Hymenoptera) act as a ‘communal stomach’, digesting solid food provided by workers and regurgitating it to adults (‘larval-adult trophallaxis’) in a nutritionally rich ‘saliva’. This act of donation is potentially costly to larvae, hindering their future reproductive prospects. In 1916, Émile Roubaud hypothesised that larval–adult trophallaxis is the principal attractant of adults to the nest, placing larval actions at the foundation of eusociality. Despite this extraordinary claim, larval–adult trophallaxis has received little empirical attention and, since the inception of kin selection theory, no theoretical attention. Using kin selection

methodology and agent-based simulation, we show that the development of an adult worker caste in primitively eusocial insects can occur during larval development. Small differences in larval development (e.g., in provisioning by adults or digestive ability) can drive large differences in larval and adult strategies. By modelling ‘larval altruism’ games in which larvae exhibiting higher levels of altruism (donation of resources to adults by trophallaxis) hinder their own reproductive prospects in adult life, we find a ‘larval altruist caste’ can develop prior to adult workers and that larval altruists are subsequently more likely to be adult altruists. Our results highlight the importance of larvae in social insects, and provide testable predictions for empirical research into the long-neglected role of larvae in the evolution of eusociality.

Maternally secreted protein ensures symbiont transmission in tortoise beetles

García-Lozano M¹, Emmerich C¹, Henzler C¹, Koch I¹, Lanz C¹, Ayas A¹, Pons I¹, Hipp K¹, Buttstedt A², Salem H¹

¹Max Planck Institute For Biology, ²University of Tübingen

MEETING ROOM 131, August 21, 2025, 10:30 AM - 12:30 PM

Symbiont transmission ensures the maintenance of mutualisms. Insects frequently rely on socially transferred materials to endow their offspring with beneficial microbes. Here, we characterized how tortoise beetles (Coleoptera: Chrysomelidae: Cassidinae) vertically transmit their obligate digestive symbiont, *Stammera capleta*. Tortoise beetles deposit symbiont-bearing caplets at the anterior pole of each egg during oviposition. These caplets contain spherical secretions that embed *Stammera* extracellularly and are consumed by larvae prior to hatching to initiate infection. As *Stammera* subsists outside the host for up to 11 days during transfer, a protective mechanism is essential for its survival. We discovered that these spherical secretions are primarily surrounded by a dense, fibril-like matrix composed of a host-derived protein. This protein belongs to the Yellow family and is uniquely and highly expressed in female ovary-associated glands. Functional knockdown of this protein

through RNA interference results in degenerated spheres. *Stammera* is more susceptible to desiccation in the absence of the host-derived Yellow, underscoring the critical role that this protein plays to ensure extracellular symbiont transmission in tortoise beetles. Additionally, we identified a novel organ specialized for storing these Yellow-surrounded spheres prior to egg deposition. Phylogenetic and structural analyses reveal that Yellow is shared across multiple tortoise beetle species, suggesting an evolutionarily conserved strategy for symbiont protection and transmission. Despite their diverse roles in pigmentation, cuticle formation, and nutrition in insects, Yellow proteins have not been previously demonstrated to play a role in symbiont maintenance and propagation. Our findings demonstrate the evolutionary co-option of a Yellow protein for extracellular symbiont protection, highlighting how host traits evolve to mitigate the challenges of symbiont transmission and stability.

Metabolic Division of Labour as an Evolutionary Ratchet for Social Systems

Leboeuf A¹

¹University Of Cambridge

MEETING ROOM 131, August 21, 2025, 10:30 AM - 12:30 PM

Behaviours that transmit metabolised materials from one individual to another allow the genome of one individual to influence the fitness of another. This decoupling of resource acquisition, processing, and use across individuals results in metabolic division of labour, a fundamental process underlying diverse forms of biological cooperation. I propose that metabolic division of labour through private channels of exchange serves as an evolutionary ratchet driving increasing interdependence across multiple levels of biological organisation.

Across biological systems, we observe similar patterns where routes of metabolic exchange create dependencies: parents provide nutritive secretions to offspring, endosymbionts supplement host metabolism, and mutualistic partners exchange vital nutrients. While these relationships initially evolve due to mutual benefits, the establishment of private channels for metabolic exchange initiates a

ratchet-like process of increasing commitment. As partners invest in specialised structures for metabolic transfer, they become increasingly interdependent – losing metabolic capabilities and developing dependencies. Private channels have clear risks and are often avoided, despite efficiency costs. I will discuss three main systems including endosymbioses, social insects, and vertebrate parental care.

By viewing the evolution of cooperation through the lens of socially transferred materials and their resulting metabolic interdependencies, we gain insight into both the innovations that enable cooperation and the constraints that maintain it. This perspective helps explain not only how cooperative relationships become entrenched but also why they often intensify and sometimes become fragile over evolutionary time, as these dependencies shape the ecological and evolutionary landscape.

Predictions of sexually antagonistic co-evolution extend to the molecular level of seminal fluid and female reproductive tract proteins.

Wiberg R¹, Thorson A¹, Snook R¹

¹Stockholm University

MEETING ROOM 131, August 21, 2025, 10:30 AM - 12:30 PM

Background: Sexually antagonistic co-evolution (SAC) is a potent driver of evolutionary dynamics, with males and females evolving traits that enhance their own fitness but harming the opposite sex. Theory predicts that levels of exaggeration at resistance and persistence traits should predict the outcomes of mating interactions and which sex has an advantage in sexual conflicts. SAC is well-studied phenotypically and these predictions have been confirmed. However, SAC, and the effects of molecular “exaggerations”, remain poorly understood at the genetic level. This is because the genes underlying the best examples of SAC are not well-known.

One exception is the iconic sex-peptide (SP) network in *Drosophila melanogaster*. The SP-network comprises a set of socially transferred materials - male seminal fluid proteins - that interact with proteins expressed in the female reproductive tract. These interactions mediate sexual conflicts over female re-mating rates and ovulation. Males benefit from reducing female re-mating rates and increasing ovulation to ensure and increase paternity, while females should prefer to re-mate when advantageous to do so and delay ovulation to exercise choice. These conflicts could lead to SAC between male- and female- components of the SP-network. However, the role of natural genetic (co-)variation in the SP-network in shaping these behaviours is understudied.

Materials and methods: We capitalise on this system and test the predictions of SAC at the molecular level using population genomic and isofemale line resources from wild populations of *D. melanogaster*. We first use population genomic analyses to evaluate patterns of co-variation in molecular evolution of the male- and female- components of the SP-network

across *D. melanogaster*. We identify populations where the relative degree of molecular “exaggeration” (genetic differentiation) implies an advantage in sexual conflicts to males, females, or neither sex. We then conduct (re-)mating experiments in the lab, including follow-up fitness assays, using flies collected from 6 European populations.

The hypothesis that these genes co-evolve by SAC predicts that; a) there should be co-variation in population genetic differentiation between male- and female- components of the SP-network, and b) that populations with an inferred female advantage will show higher re-mating rates and increased direct benefits (higher offspring production and reduced fitness costs) to females compared to populations with inferred male advantage.

Results: We find strong support for both of our main predictions. We find strong support for co-variation, indicating co-evolution between the loci. Populations with an inferred female advantage show higher rates of re-mating than populations with an inferred male advantage. Moreover, female-advantage populations also have a longer time until the peak of offspring production, reflecting a slower rate of ovulation. This pattern suggests that females may be more able to resist also the ovulation inducing effects of SP.

Conclusions: Our study highlights the importance of considering co-evolution between donors and recipients of socially transferred materials. We show that patterns of molecular co-evolution between the transferred male seminal fluid proteins and proteins of the female reproductive tract predict outcomes of mating interactions. Our findings support a role for SAC in the evolution of these molecules and, for the first time, extend SAC theory to the molecular level.

POSTER SESSION 3 - P03.130, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

A common feature of domesticated animals is a shortening and widening of the skull, along with reduced brain size, tooth size and body mass. Fortunately, skulls tend to be well preserved in large numbers in natural history collections, documenting variation in wild species and their domestic relatives over time and space. When combined with genomic data, this material presents a valuable opportunity to reconstruct the timing and sequence of events during domestication, including genetic, morphological and behavioural changes. Here, we present a matched genome-phenome library of wolves (*Canis lupus*) and dogs (*Canis familiaris*) spanning ~350 individuals, including >100 dog breeds and >200 wolves collected across 19 countries. MicroCT scanning was used to generate high-resolution 3D skull models, paired with whole genome sequencing for each individual. We exploit this database to

explore canid skull morphology and its genomic basis using automated landmarking tools, to assess how domestication influences fine-scale shape variation as well as skull asymmetry, modularity and integration. We use GWAS to identify key genomic regions associated with skull evolution, and to interrogate loci known to influence skull shape in dog breeds. Integration of these unique, yet complementary datasets will allow us to investigate complex evolutionary processes, and to pinpoint signatures of selection in skull morphology associated with domestication. Our approach provides a new template for the integration of genomic and morphological data in the study of evolutionary processes, particularly for when genetic and morphological data disagree.

Applying ancient DNA extraction methods to improve the recovery of genomic material from modern bone samples

Schuh A¹, Essel E², Housman G³, Gunz P¹

¹Department of Human Origins, Max Planck Institute for Evolutionary Anthropology, ²Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, ³Department of Primate Behavior and Evolution, Max Planck Institute for Evolutionary Anthropology

POSTER SESSION 3 - **P03.110**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Gene regulation plays a central role in shaping the developmental and evolutionary morphology of the skull. DNA methylation has emerged as a powerful proxy for inferring gene regulatory activity across tissues. However, our understanding of intra- and inter-individual variation in gene regulation within the craniofacial skeleton remains limited. This gap is partly due to the rarity of opportunistically available skeletal tissues from deceased individuals and the inherently low cellular density of bone, which restricts the recovery of genomic material. As a result, extracting DNA from small craniofacial bone samples – even those from well-preserved modern specimens – remains technically challenging, requiring careful optimization to maximize yield and quality. Here, we conducted a pilot study to assess whether ancient DNA extraction methods can be successfully applied to modern craniofacial bone samples to recover genomic material.

We obtained a wild boar skull with a known postmortem interval and a pig skull sourced from the food industry, and froze these specimens at -80°C. Bone cores (N = 8) were extracted from various craniofacial regions using a 50 mm diameter drill. Cortical bone was separated from trabecular bone with sterile scalpels, and any remaining soft tissue was removed by washing the cores in PBS. Bone powder was then prepared from each cortical bone sample using a freezer mill. We applied and compared two DNA extraction protocols, both designed to maximize DNA recovery: a manual phenol-chloroform method previously used on ancient and modern bone samples (Method 1) and a silica-based method optimized for ancient bone (Method 2). DNA yield and quality were assessed using a Qubit fluorometer and an Agilent TapeStation, respectively.

When accounting for the initial amount of bone powder, Method 2 consistently yielded significantly more DNA than Method 1 (average total amounts: 2535 ng versus 318 ng, respectively; p-value: 0.004). Moreover, Method 1 was less reliable and sometimes failed to recover any DNA (3 out of 8 samples). Despite lower yields, Method 1 exclusively recovered long DNA fragments (average size: 30616 bp), as opposed to Method 2 which recovered both long and short DNA fragments (range: 590-25447 bp). These fragment size distribution differences are further reflected in the resulting DNA Integrity Numbers (DIN), with the average score of 7.9 for Method 1 being higher than the average score of 4.9 for Method 2. Although Method 2 retained many small DNA fragments, large fractions of the total DNA also contained long fragments (average size: 21169 bp) which have comparable lengths to those recovered in Method 1 (p-value: 0.8).

Applying Method 2 resulted in significantly higher DNA yield than Method 1, but also recovered a broader distribution of fragment sizes. This aligns with our expectations, as both methods were originally developed for ancient DNA recovery, but Method 2 has been specifically optimized to capture highly degraded DNA with small fragment sizes. Overall, our primary goal is to maximize DNA yield from small bone samples, while not substantially sacrificing on DNA quality. We show that Method 2 enables consistent recovery of sufficient DNA yield and quality for downstream applications. Moving forward, we plan to expand our testing of Method 2 to craniofacial skeletal tissues from a broader phylogenetic distribution of species with different degrees of preservation to investigate variation in skeletal DNA methylation patterns.

Biomechanical adaptation to an anthropogenic diet in a human-commensal bird

Fawthrop R^{1,2}, Herrel A^{3,4,5,6}, Sætre G⁷, Pacheco G⁷, Gavrilov A⁸, Ravinet M⁷, Rowe M¹

¹Netherlands Institute of Ecology (NIOO-KNAW), ²University of Groningen, ³Muséum National d'Histoire Naturelle, ⁴Ghent University, ⁵University of Antwerp, ⁶Naturhistorisches Museum Bern, ⁷University of Oslo, ⁸Institute of Zoology

POSTER SESSION 3 - **P03.115**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The vertebrate craniofacial system plays a pivotal role in many ecological contexts including defence, mate acquisition, and feeding. Performance traits, such as bite force, provide valuable insights into the relationship between variation in craniofacial morphology and the ecological niche of populations. The anthropogenic niche is characterised by human-induced modifications in resource availability, for example the introduction of novel foods or increased abundance of human foods. Populations which depend upon these human resources, known as human-commensals, therefore provide a fascinating opportunity to consider craniofacial evolution within the context of dietary adaptation to human-modified environments. The house sparrow (*Passer domesticus*) is a globally distributed human-commensal species, found in human-modified environments across the world. The species' association with humans arose during the Neolithic, when human societies transitioned from hunter-gatherer to agricultural-based lifestyles. This increased human association likely led to a change in feeding ecology, specifically an increased reliance on tough, domesticated cereal grains such as wheat. Whilst previous genomic analyses have identified signatures of selection on genes associated with

craniofacial morphology in human-commensal populations, the phenotypic implications of this remain unexplored.

We determined whether a transition to a hard, anthropogenic seed diet is associated with adaptive changes in the structure and function of the feeding apparatus in house sparrows. Firstly, we used a combination of faecal metabarcoding and stable isotope approaches to characterise the diet of human-commensal and non-commensal sparrow populations. We then related dietary differences between populations to measurements of bite force, skull and beak morphology, and jaw muscle architecture.

As predicted, we observed stronger bite forces in human-commensal populations, associated with important changes in craniofacial morphology, including increased head width and beak depth. Furthermore, we identified differences in underlying jaw muscle architecture, including increased jaw muscle mass in human-commensal populations. Taken together, our findings show dietary transitions are associated with morphological and biomechanical adaptation, highlighting the importance of craniofacial evolution in the ability to thrive in human-modified environments.

Ecomorphological diversification of Caviomorph rodents and the role of environmental change as a driving force

Aparicio De Soto M^{1,2}, Goswami A², Day J¹

¹University College London, ²Natural History Museum

POSTER SESSION 3 - **P03.129**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Adaptive radiations are regarded as a major driver of biological diversity and ecomorphological disparity. These radiations are initiated by ecological opportunity, where intrinsic innovation can be exploited to occupy new niches. The generation of new available niches might depend on external factors, such as environmental changes or the colonization of new geographical regions. Caviomorpha, an infraorder of Neotropical rodents, is characterized by both its high species richness and its eco-morphological disparity, and is considered an example of an adaptive radiation. This clade diversified in South America during a period of profound environmental change. Although events such as the Eocene-Oligocene transition cooling and the uplift of the Andes have been proposed as potential drivers of caviomorph diversification, direct assessments of their role on the evolution of phenotypic diversity remain limited. Additionally, during this diversification process, Carpomyinae, a clade within Caviomorpha, arrived and diversified in the Caribbean Islands. Despite this, a comparison of shape evolution between continental groups and those which later diversified in the islands has not been investigated. This clade provides an opportunity to not only study the effects of environmental change in phenotypic diversification, but also to compare the effects of these in both continental and insular settings.

To address these knowledge gaps, we compare phenotypic diversification in Caviomorpha with temporal changes in environmental variables. We assessed cranial and mandibular shape diversity for 170 species of caviomorph rodents (68% of the total diversity) using landmark-free 3D geometric morphometrics. Appendicular morphology was analysed through the measurement of continuous linear traits in 58 species. Principal

component analyses (PCA) were generated from these data to examine the phenotypic diversification over time, using phylogenetic comparative methods to investigate trait evolution. This also included the fitting of different evolutionary models, including a Brownian Motion model, an Early Burst model, and two different Ornstein–Uhlenbeck models where the long-term mean is dependent on two key environmental variables: temperature and Andean elevation rates.

Preliminary analyses show a strong phylogenetic signal and a clear separation of the families in the morphospace. Echimyidae, the most species-rich family, shows a clear separation in postcranial shape between continental clades and the insular clade Capromyinae, which contrasts with previous studies on mandibular morphology. Ctenomyidae, the second most species-rich family, shows a high morphological diversity compared to other groups, despite its seemingly ecological homogeneity. Model fitting also allows for understanding of how external variables may drive phenotypic diversification in this key mammalian clade and contribute to creating new ecological opportunities.

This study provides deeper insights into the relationships between the environment and the origins of ecological diversity, particularly in the context of major environmental transitions and the diversification events generated by them. The study also provides a comparison of the diversification process between the mainland and in island environments, and how different geographical contexts shape phenotypic evolution. It further underscores the importance of examining both internal and external drivers in adaptive radiations and highlights how these radiations represent complex interactions between the environment and the species involved.

Evidence for tonotopic organization in zebrafish otolith organ: Implications for the evolution of vertebrate auditory systems

Tanimoto M^{1,2}, Higashijima S^{1,2}

¹National Institute for Basic Biology, ²Exploratory Research Center on Life and Living Systems (ExCELLS)

POSTER SESSION 3 - P03.133, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Auditory information is vital for many animals. Frequency discrimination of sound is fundamental to auditory perception. In terrestrial vertebrates, different frequencies of sound are encoded and processed by hair cells (HCs) in the auditory sensory organs (e.g., cochlea in mammals) and brain neurons that are spatially orderly arranged, forming tonotopic maps. How this frequency-selective response regionalization emerged in the process of diversification of vertebrate species remains an open question. Since both the auditory and vestibular systems are thought to have evolved from a common ancestral sensory system, comparative analysis of acoustic-vestibular systems across species offers key insights into this evolutionary process. The otolith organs in the inner ear primarily function as linear acceleration detectors. These organs contain a specialized region called the striola, which is characterized by distinct morphological and physiological properties of HCs. The striolar HCs transduce phasic stimuli, allowing them to detect rapid changes in head acceleration. Fish hear sound using their otolith organs, although they do not have the cochlea. Although frequency-selective regionalization in fish otolith organs has been indirectly suggested, neural activity patterns during various frequencies of the stimulus remain unknown.

Materials and methods: To address how otolith organs respond to various frequencies of vibration, we developed microscope and stimulus apparatuses to image neural activity during vibratory stimulus. This stimulus mimics head motion and the particle motion

component of sound in water. We used larval zebrafish as a model organism to image HC activity in vivo (Tanimoto et al., Nat. Commun., 2022). We applied sinusoidal acceleration in a single axis with frequencies ranging 1 and 1,000 Hz, which enabled systematic characterization of the frequency response.

Results: In vivo Ca²⁺ imaging revealed spatially segregated, frequency-dependent responses in HCs in the utricular otolith organ of zebrafish larvae. Low frequency vibration (<20 Hz) activated most HCs that have hair bundle polarity parallel to the stimulus axis except a small number of HCs in the striola. As the vibration frequency increased, responsive HCs became confined to the striola region. Higher frequency vibration activated only a small population of HCs in the striola that did not respond to the low frequency stimulus, demonstrating a clear tonotopic organization.

Conclusions: These results demonstrate the presence of tonotopic organization in the fish otolith organ. Given the high conservation of vestibular organ structure and function across vertebrate species, our findings suggest that tonotopy represents an ancestral feature acquired in the common vertebrate ancestor, although the independent acquisition of tonotopy in fish through convergent evolution cannot be completely ruled out. This study provides important evolutionary insights into the acquisition of acoustic frequency discrimination in vertebrate auditory systems.

Evolutionary dynamics of gene and isoform regulation underlying jaw diversification in parallel cichlid adaptive radiations

Singh P¹, Ahi E², Duenser A³, Seehausen O¹, Sturmbauer C⁴

¹University Of Bern, ²University of Helsinki, ³Institute for Freshwater Ecology and Fisheries Management,

⁴University of Graz

POSTER SESSION 3 - **P03.098**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Cichlid fishes exhibit extraordinary craniofacial diversity that allowed that to rapidly adapt to novel niches as ecological opportunity arose. While it is generally accepted that variation in gene expression (GE) contributed to this process, it is less understood how alternative splicing (AS), a major source of transcriptional variation, shaped this diversity. Here we investigate the landscape of AS and GE in the oral and pharyngeal jaws of three iconic adaptive radiations of African cichlid fishes that evolved divergent and convergent trophic adaptations within <16,000 to 3.8 million years. We show that jaws of ecologically divergent species from younger radiations exhibit greater differences in splicing than those from the older radiation. Most of these differentially spliced isoforms that shaped diverse jaws arose from ancestral standing variation, which was also expressed at low levels in non-radiating species, and increased in frequency during the adaptive radiation process. We identified several

novel isoforms associated with cartilage development that emerged within each lake radiation and were differentially incorporated in the jaws of herbivorous vs. carnivorous species. While hundreds of genes were differentially expressed and spliced between divergent jaws, only a handful of genes were repeatedly used to give rise to similar jaw shapes in three cichlid radiations. Furthermore, we found that the parallel modular expression of thousands of genes may underlie the differences between the functionally decoupled oral and pharyngeal jaws across all three cichlid radiations. Of note were genes from the *alx* craniofacial skeletogenesis transcription factor family (*alx1*, *alx4*), of which *alx1* is associated with beak divergence in Darwin's finches. We suggest that a complex interplay of GE and AS underlies jaw diversification cichlid adaptive radiations, with differences in splicing arising from ancestral variation enabling rapid ecological diversification during speciation.

Exploring the genetic correlations of craniodental size dimensions in a pedigreed baboon colony

Modesto Mata M^{1,2}, Thiebaut A¹, Cheverud J³, Mahaney M⁴, Joganic J⁵, Hlusko L¹

¹CENIEH, ²UNIR, ³Loyola University Chicago, ⁴University of Texas Rio Grande Valley School of Medicine ,

⁵National Park Service

POSTER SESSION 3 - P03.106, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Phenotypic correlations between cranial and dental traits have long been central to primate paleontology and osteology. While quantitative genetic approaches have clarified the genetic basis of variation in either cranial or dental traits independently, few studies have investigated both anatomical regions simultaneously. In this preliminary study, we assess genetic correlations among craniodental traits in a captive baboon pedigree from the Southwest National Primate Research Center (Texas, US). We analyzed linear measurements reflecting neural crest-derived structures (teeth and face) and mesodermally derived structures (posterior cranium), using datasets comprising 985 crania and 632 dentitions. Two facial, two posterior cranial, and molar mesiodistal and buccolingual dimensions were included. Pairwise analyses were based on an average of ~500 individuals for whom we have both cranial and dental data. Phenotypic, genetic, and environmental correlations were estimated

using a maximum likelihood approach implemented in SOLAR-Eclipse.

Our results reveal significant genetic correlations between molar length and both anterior and posterior cranial dimensions, including the sagittal diameter of the foramen magnum ($RhoG = 0.35$) and the prosthion-nasion distance ($RhoG = 0.32$; both $p < 0.0001$), suggesting incomplete pleiotropy. We found no evidence of environmental correlations among traits, indicating that shared environmental influences do not explain the observed phenotypic associations. Additionally, there is no clear pattern suggesting that adult phenotypic correlations align with differences in embryonic tissue origin. These findings provide preliminary evidence of genetic integration between dental and cranial traits and offer new insights into the co-evolution of the primate skull and dentition.

Heterochronic shift in gene expression contributed to the evolution of vertebrate sensory system

Sato S¹

¹Jichi Medical University

POSTER SESSION 3 - **P03.102**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Several different sensory organs and sensory neurons have arisen during vertebrate evolution. In the trunk region, cyclostomes have simple intramedullary mechanosensory neurons called Rohon-Beard (RB) neurons while amniotes possess complex extramedullary neurons in the dorsal root ganglia (DRG). Intriguingly, in the fish and amphibians, the sensory system of the trunk switches from RB neurons to DRG neurons during development. However, except the fact that RB and DRG neurons originate from neural crest or progenitor cells, the mechanisms underlying the phylogenetic transition and the ontogenic switching remain unknown. In *Xenopus*, overexpression of the SIX1 homeodomain protein promoted early apoptosis of RB neurons and the emergence of extramedullary sensory neurons, whereas knockdown of *six1* delayed the reduction of RB neurons. A sensory neuron-specific *Six1* enhancer identified in the mouse activated

transcription in *Xenopus* RB neurons earlier than endogenous *six1*. To confirm SIX1 function in intramedullary and extramedullary neurons was essentially unchanged, we analyzed mice deficient for *Six1* and paralogous *Six4*. The *Six1/4*-deficient embryos have intramedullary sensory neuron-like cells of neural crest origin and immature DRG neurons. The forced expression of SIX1 in the neural crest-lineage of *Six1/4*-deficient embryos partially rescued the phenotype. These results established the conserved role of SIX1 and suggested that the onset of SIX1 expression during sensory development in the amniote lineage shifted earlier after the divergence from amphibians. We suggest that the heterochronic shift in *Six1* expression contributed to the transition of trunk sensory differentiation and architecture, and hence to the evolution of trunk sensory system in vertebrates.

Parallel adaptation of tooth classes to dietary niches in Chiropterans

Gagliardi F¹, Moison B¹, Grossnickle D², Sears K³, Santana S⁴, Sadier A¹

¹CNRS, ISEM, Université de Montpellier, ²Natural Sciences Department, Oregon Institute of Technology,

³Department of Ecology and Evolutionary Biology, University of California, ⁴University of Washington

POSTER SESSION 3 - P03.136, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Mammalian tooth classes are considered a key innovation that has allowed mammals to colonize new dietary niches and diversify. From the conical shape of the earliest homodont teeth, mammals have evolved four distinct tooth classes (incisors, canines, premolars, and molars), each having a specialized morphology adapted to a specific function during food processing. While tooth classes are widely used in paleontology and for species identification, our understanding of the morphological signals that characterize the identity of each tooth class remains limited. To address this gap, we use the evolutionary radiation of Noctilionoid bats including Phyllostomids, as a model system. This superfamily is ideal to study these questions as these bats possess a complete mammalian dentition with four tooth classes and have radiated into nearly every mammalian ecological dietary niche (carnivore, frugivore, insectivore, nectarivore, omnivore, and sanguinivore) resulting in a huge variation in tooth number and shape.

We first characterized the precise morphological signature of two tooth classes, premolars and molars. To do so, we established a precise morphospace for each lower post-canine tooth across 151 species of Noctilionoid bats. We used a geometric morphometric approach incorporating two distinct sets of landmarks, 3 curves of semi-landmarks and 11 single-point landmarks,

for premolars and molars respectively. For both tooth classes and all teeth, we found that the species generally clustered by dietary niches, and separated along two main PCs that correspond to the height of the cusps and the width of the tooth. Interestingly, while some convergent patterns are observed for nectarivores and faunivores, stenodermatinae cluster in the same area of the morphospace indicating that their morphology retains a strong phylogenetic signal. When calculating disparity for each tooth, we found that premolars tend to have a significantly higher disparity than molars. Within tooth classes, we found an increase in disparity from the first molar m1 to the last molar m3 and that the middle premolar p3, when present, is more variable than p2 and p4, which is reminiscent of their timing of induction during development.

Together, these results reveal that premolars and molars evolved in tandem, exhibiting distinct but also overlapping patterns during their diversification. While they follow similar evolutionary trajectories in response to dietary adaptations, they exhibit clear differences that constitute a precise morphological signature for each tooth class, representative of tooth class identity. More broadly, these results provide insight about the diversification of repeated structures within and between classes.

Influence of Morphological Integration and Modularity on Evolutionary Rates and Disparity of Bird Beaks

Ely R¹, Hipsley C¹, Sommer S¹, Nielsen R²

¹University Of Copenhagen, ²University of California

MEETING ROOM 118+119, August 21, 2025, 2:00 PM - 4:00 PM

The bird beak is a multifunctional innovation, having facilitated adaptations to a plethora of ecological niches, resulting in a grand evolutionary radiation currently represented by over 11,000 bird species. The sheer disparity of bird beak morphology implicates the role of evolutionary constraints stemming from magnitude (integration) and patterns (modularity) of trait covariance. We aim to evaluate potential associations between morphological integration and modularity on evolutionary rates and disparity at macroevolutionary scales in the avian bill. If integration and modularity act primarily to influence evolutionary constraints, the expectation is that rates and disparity should be negatively correlated with the degree of integration, and it is commonly posited that a positive association between modularity and rates and disparity exists. To explore these expectations, we leverage the vast taxonomic scale of the MarkMyBird dataset, represented by 3D semilandmarks along the culmen and tomia of 8748 avian species. All analyses were performed using phylogenetic comparative methods, employing a new avian supertree whose higher-level relationships are heavily weighed in favor of a relatively new and highly resolved phylogenomic avian tree. We performed analyses of morphological integration using the standardized effect size of relative eigenvalue variance and estimated evolutionary rates and disparity under Brownian Motion (BM) assumptions. Disparity was estimated using a special reinterpretation of the common BM evolutionary rate (σ^2), noting that standard functions to estimate σ^2 essentially yield estimates of phylogenetically transformed trait variance if the phylogeny is scaled to unit height a priori. Modularity was assessed by using the effect size of the covariance ratio, under the assumption that two modules drive the covariance structure of the bird beak consistent with numerous evo-devo studies. Modular analyses require a priori specification of

individual landmark assignments to hypothesized modules, as such we used Ward's linkage dendrogram based on landmark correlation matrices to detect most likely landmark assignments to modules. Evolutionary rates, disparity, integration, and modularity were analyzed per taxonomic order. Using phylogenetic generalized least squares, disparity and rates were positively and significantly correlated with the magnitude of morphological integration, such that higher rates and greater disparity are associated with greater trait integration (rates: $R^2=0.174$, $p=0.013$; disparity: $R^2=-0.392$, $p=1e-4$). The magnitude of modularity and rates and disparity were not significantly correlated (rates: $R^2=-0.038$, $p=0.82$; disparity: $R^2=-0.039$, $p=0.88$). The apparent positive association between rates, disparity, and integration is unexpected, counter to intuitive expectations that greater integration results in greater evolutionary constraints, thus resulting in limited morphological disparity and lower rates. Such relationships between integration and rates and disparity have been shown in other clades, falling under theoretical expectations of the 'facilitation hypothesis' and evolutionary lines of least resistance. Beak modularity does not appear to impact rates or disparity, indicating that either alternative modular hypotheses regarding the number of modules may need to be evaluated, or that the modular architecture and magnitude across avian orders remains invariant while the degree of overall integration is allowed to vary, consistent with expectations from mammalian modularity and integration studies. Indeed, across all avian orders the two-module landmark scheme estimated via Ward's linkage dendrogram consistently retrieves a ventral module including the beak tip, and a dorsal module composed largely of nasal traits. Such a pattern is qualitatively consistent with classic evo-devo studies of finch beaks, showcasing its potentially broadly conserved phylogenetic presence.

Neural crest biology shapes evolutionary dynamics of the lacertid skull across evolutionary scales

HORTA-LACUEVA Q¹, Uller T¹, Flecks M², Gabelaia M², Hispley C³, Kirschner M⁴, Müller J⁴, Vehof J², Feiner N^{1,5}

¹Lund University, ²Museum Koenig Bonn Leibniz-Institut zur Analyse des Biodiversitätswandel, ³University of Copenhagen, ⁴Museum für Naturkunde Leibniz-Institut für Evolutions- und Biodiversitätsforschung, ⁵Max Plank Institute for Evolutionary Biology

MEETING ROOM 118+119, August 21, 2025, 2:00 PM - 4:00 PM

Background: The contrasting pleiotropic properties of the neural crest cells and the mesoderm, from which vertebrate skull bones are derived, likely modulate variation that is available to selection and thereby influence head shape evolution. Whether and how the influence of the dual developmental origin of the skull on evolution lasts beyond the population level and contributes to species diversification remains to be established.

Material and methods: We conducted 3D morphometric analyses with X-ray microtomography (CT) scans of lacertid skulls at two evolutionary scales. At the microevolutionary scale, we focused on the common wall lizard, *Podarcis muralis*, exhibiting a suite of exaggerated traits partially developing from neural crest cells, which has been termed the nigriventris syndrome. At the macroevolutionary scale, we compared 174 species of the lacertid family (44% of the described species).

Results: In the common wall lizards, we identified two modules of phenotypic covariance corresponding to the neural crest- and mesoderm-derived bones. The

neural crest module contributed more than the mesoderm to the differences in skull shape between the lizards exhibiting the nigriventris syndrome and the specimens with the ancestral phenotype. At the level of the lacertid family, we also observed modularity corresponding to neural crest- and mesoderm-derived bones. However, the neural crest derived module showed slower evolutionary rates and less disparity.

Conclusion: The primary importance of the neural crest for the evolution of the nigriventris syndrome at the population level contrasts with the macroevolutionary patterns in lacertids that suggests a more limiting role of the neural crest in diversification at the family level. We suggest that developmental properties of body parts, like those emerging from the neural crest-mesoderm duality generate stable covariance structures and influence evolvability across evolutionary timescales. However, the realized variation within this covariance structure may vary across levels, depending on external factors like correlational selection, which complicates views on the consistency between micro- and macroevolution.

Prenatal Hormones Shape Maternal–Fetal Morphological Integration in a Model of Cephalopelvic Covariation

Zaffarini E¹

¹University Of Calgary

MEETING ROOM 118+119, August 21, 2025, 2:00 PM - 4:00 PM

The risk of mismatch between fetal head and maternal birth canal in humans is supposed to be greatly reduced by the presence of morphological co-variation between these traits. Neonates that inherit a large head size from their mother are less likely to obstruct labour provided that their mother also possesses a comparably wide birth canal. This high degree of morphological covariation in humans reflects an evolutionary compromise between the need for a large birth canal to accommodate large neonates and the need for a narrow canal to support pelvic floor muscles and enable efficient bipedal locomotion.

Recent studies have shown that this pattern of covariation between maternal pelvis and fetal head is also present in macaques, indicating that it is not uniquely human but may characterize other primates that birth large offspring.

Here, we extend this line of inquiry to a non-primate, quadrupedal species that gives birth to relatively small neonates: the common house mouse (*Mus musculus*). Using geometric morphometrics, we examined within-individual covariation between skull and pelvic morphology across several wild-captured and laboratory mouse strains. Our results reveal significant covariation between neurocranial size and pelvic shape, with larger skulls associated with wider and rounder pelvic canals, and smaller skulls associated with narrower ones. Strikingly, the pattern of skull–pelvis covariation in mice mirrors that observed in humans, suggesting a conserved developmental mechanism across mammals, independent of neonatal size or locomotor mode.

To investigate potential developmental mediators of this integration, we tested whether prenatal sex steroids influence the

relationship between maternal pelvic shape and fetal head morphology. Pregnant C57BL/6 mice were treated with exogenous estrogen or testosterone between embryonic days E12.5 and E17.5, a critical window for skeletal development. We then measured covariation between maternal pelvic shape, fetal head shape, and fetal size across treatment groups.

Hormone exposure significantly alters patterns of skull–pelvis covariation. Both estrogen and testosterone treatments modified the degree and direction of integration between maternal and fetal morphology, indicating that prenatal hormonal environments can modulate the developmental architecture underlying cephalo–pelvic covariation.

Together, these results challenge the prevailing view that skull–pelvis covariation evolved solely in response to the obstetric constraints of large-brained primates. Instead, we show that this integration is present in a quadrupedal species with small neonates and may reflect a more general principle of coordinated morphological development. Moreover, our hormone manipulation experiments highlight a possible mechanistic link between endocrine signaling and the establishment of intergenerational morphological integration during pregnancy.

Reconciling stemness and specialization in neural crest cells drives avian beak diversification

Sánchez Moreno C¹, Badyaev A¹

¹Department of Ecology and Evolutionary Biology, University of Arizona

MEETING ROOM 118+119, August 21, 2025, 2:00 PM - 4:00 PM

Multicellular development must balance organismal integration with tissue differentiation. Migratory stem cells often fulfill these dual needs by orchestrating region-specific tissue differentiation, yet how they balance stemness with positional specificity is unclear. Using novel analytical approaches capable of tracing millions of cells throughout avian beak development, we discovered a transient phase of "local mimicry" in migratory neural crest cells in which they briefly match protein profiles of the overlying epithelium. This "local mimicry" phase temporarily extends region-specific epithelial signaling, creating distinct boundaries that trap later arriving neural crest cells and seed localized cell condensations. Accumulation and

mixing of cells in these condensations lead to their morphological and molecular homogenization, erasing initial regional differences impaired by epithelial protein matching, thus restoring their multipotency and priming site-specific differentiation. These cycles of transient specialization and uniformity – driven by universal processes of cell proliferation and migration – allow neural crest cells to interpret evolutionarily conserved mesenchyme-epithelial signaling in a region-specific manner without compromising their stemness. By reconciling global integration and local specialization and enabling modular recombination of regulatory circuits, this developmental organization facilitates the remarkable evolutionary diversification of avian beaks.

Disentangling the complex network of phage-host interactions at genome resolution in freshwater

Davies L¹, Grujic V¹, Silva Kavagutti V¹, Goodarzi Z¹, Mehrshad M¹

¹SLU- Swedish University of Agricultural Sciences

POSTER SESSION 1 - **P01.129**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Bacteriophages are the most abundant and genomically diverse biological entities on the planet.

Bacteriophages and their dependence on their bacterial host has defined the evolutionary trajectory of both parties for millennia. Additionally, bacteriophages are an important contributor to gene flow in the environment through horizontal gene transfer. Bacteriophage genomes are constantly reshaping due to mutations and through their role in horizontal gene transfer which is consequently affecting their host range and impact on bacterial community. Phages also exert top-down control on dominating bacteria, influencing the species equilibrium dynamics and nutrient cycling in the surrounding ecosystem. High-throughput metagenomic studies have elucidated the vast diversity of phages in aquatic ecosystems including both marine and freshwater environments. However, the depth of characterization is greater for marine phage communities currently. Freshwater ecosystems have complex seasonal and vertical profiles throughout the year, changing in temperature and nutrient composition and housing microbial communities that are distinct from marine ones. This spatial and temporal diversity of phages and their direct impact on bacterial community dynamic in freshwater ecosystems is not yet fully characterised.

Freshwater ecosystems host a diverse community of phages, however, we cannot confidently assign phage to their respective host based on indirect linkage from

metagenomic data alone. Current metagenomic methods fail to resolve the complex nature of phage-host interaction networks and dynamics, undermining our ability to disentangle ecological relevance and evolutionary impact of phages in freshwater environments. With a lack of cultured references, we need to couple multiple high-throughput techniques in order to resolve a confident phage-host interactions network at community level.

In this study, we are collecting samples with high temporal resolution (twice a week for six consecutive weeks) from freshwater Lake Erken in Sweden. Collected samples were concentrated in different size fractions of 0.1 µm for bacteria and 30kD for viruses using tangential flow filtration. The concentrated bacteria and virus fractions were then exposed to each other to induce phage-bacteria interactions. These incubations were then filtered, and the collected biomass was used for short read Illumina and long read Pacbio sequencing to reconstruct high quality phage and bacterial genomes. In addition to in-silico host designation methods, in this study we will apply high-throughput single cell genomics to the incubations to resolve phage-host interactions and generate a confident network of phage-bacteria interactions. This confident network of phage-host interactions will enable a detailed understanding of the impact of phages in the flow of genetic material among freshwater bacterial community.

Diverse patterns of transposable elements expressions in *Macaca mulatta* and the regulation of gene expression in adjacent genes by tissue-specific TEs

Kim E¹, Park K², Lee S², Kim D^{1,2}

¹Bioscience, Korea University of Science and Technology, ²Korea Research Institute of Bioscience & Biotechnology

POSTER SESSION 1 - **P01.118**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements (TEs) consist of approximately half of the primate genomes and may affect gene regulation in various ways resulting in the evolution of phenotypic diversity. Recently, it has become obvious that TEs play an invaluable role in physiological and pathological processes. Since TEs have regulatory motifs, they can act as regulators of gene expression. However, their expression and regulation across tissues are not clear.

Here, we analyzed TEs expression in 13 different tissue types of the rhesus macaque (*Macaca mulatta*), the most widely used non-human primate model as a human replacement, of a public RNA-seq dataset to investigate their participation in gene regulation and difference in each tissue. We also analyzed Cap analysis gene expression (CAGE) datasets of 14 different tissue types to attain CAGE transition start sites (CTSS). We show that TEs are not randomly distributed in the rhesus macaque genome, but are enriched differently depending on their genomic location. Most TEs in intergenic regions are silenced, and highly

expressed TEs are remarkably enriched in the thymus. Not only are four clusters of TEs found in various tissue types, but enrichment patterns are followed by tissue types and age of TEs. Particularly, 365 and 269 short interspersed nuclear elements (SINEs) and long interspersed nuclear elements (LINEs) are highly enriched in transcription start sites (TSSs), respectively, which may be potential regulatory activities. Additionally, we found 37 and 1226 tissue-specific TEs that are highly expressed on coding DNA sequence (CDS) and upstream, respectively, which may drive the overexpression of adjacent tissue-specific genes.

In summary, we present diverse patterns of TEs in rhesus macaques across 13 different tissues. Based on the analysis of pairwise comparisons and association between TEs and genes, we identified tissue-specific TEs in CDS and upstream regions where their nearby genes were also highly expressed. Our study will improve the understanding of TEs as regulators of nearby gene expression in a tissue-specific manner in primates.

How TEs dynamics follow lifestyle transitions in gall wasps (Hymenoptera: Cynipoidea)

Feng J¹, Branca A¹

¹University Paris Saclay

POSTER SESSION 1 - **P01.121**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements (TEs) are selfish genetic elements that can replicate themselves and cause mutations by inserting into different loci in the host genome. TE insertions may also lead to non-allelic homologous recombination (NAHR), creation of novel regulatory sequences, and epigenetic changes. TEs inserted into introns interfere with the normal splicing pattern of precursor mRNAs, triggering various forms of selective splicing. For instance, insertion of Tgmt-CACTA TE into intron 1 of the Flavonoid 3'-hydroxylase gene in soybean which produced the t* allele, the gene that determines gray trichome color. In the British peppered moths, a TE insertion in the intron of the cortex gene increases its expression, leading to an alteration in the moths' body color.

The ability to form galls is a convergent trait in insects that has evolved independently several times in different orders. Gall wasps (Hymenoptera: Cynipoidea) comprise many species inducing galls on several host plants and, in addition to true gall inducers, they also consist of phytophagous inquiline, which live inside the gall tissue induced by gall wasps or other insects and parasitoid species. Cynipoidea species show an important variation in genome size (from 150 Mbp to up to 2.5 Gbp) highly correlated with differences in TE content. Noticeably, we

found that genome size correlates better with lifestyle, namely gall inducer, inquiline and parasitoids, than with phylogeny. We therefore investigated how TE dynamics could have played a role in or be influenced by the transition toward different lifestyle in Cynipoidea.

Twenty-nine species were selected to represent the different lifestyles and main clades of Cynipoidea. De novo detection and annotation of TEs was performed using a custom pipeline.

A total of 56,237 consensus sequences for repeats were reconstructed and our data suggest that intron size in Cynipidae appears to correlate with the number of transposons, with Gall inducers having a larger average intron size compared to Inquiline. Notably, Tc/Mariner elements seem to have played a particular role in intron size change in the different life styles, the gall inducing species having the largest introns. We have yet to determine if these convergent changes are the result of independent invasion of different families or horizontal gene transfer of the same family. We will also analyze how the change in intron size could have affected the expression of particular genes involved in gall induction.

Key words: Transposable element, Cynipidae, life lifestyles, convergent invasions, Gall inducers, Inquiline.

Mechanisms of infection in freshwater bacteria–phage systems

Grujic V¹, Mehrshad M¹

¹Department of Aquatic Sciences and Assessment, Science for Life Laboratory, Swedish University of Agricultural Sciences

POSTER SESSION 1 - P01.126, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Viruses are typically considered to outnumber their microbial hosts, often by an order of magnitude, particularly in productive freshwater lakes. Through their top-down control on bacterial populations, phages influence not only microbial dynamics and evolution but also biogeochemical cycles. While high throughput metagenomic approaches have revealed a vast diversity of phages specifically in aquatic ecosystems, they are inefficient in connecting these phages to their respective host and revealing their infection strategies. Cultured phage-host systems bypass this limitation, but they remain biased by the great plate count anomaly themselves. Majority of ecologically relevant freshwater bacteria are still very cumbersome to culture and their interaction with their hosts remain enigmatic.

In this study, we developed a culture collection from the eutrophic Lake Ekoln in Sweden. Samples were collected monthly from August 2024 to February 2025 (five time points in total), and dilution-to-extinction cultures were established using modified NSY medium. For each sampling point, six 12-well plates (72 wells total) were inoculated with ~1 cell. Success rates varied by season, ranging from 2.7% to 38%, and overall, approximately 40% of wells were successfully cultivated, yielding 113 positive cultures.

Each isolate is undergoing three rounds of dilution-to-extinction to ensure axenic and clonal cultures. When cultures are purified and stable, their taxonomy is assigned using Sanger sequencing and universal primers 27F and 1492R, targeting 16s rRNA gene. We have currently characterized isolates from August, September, and October. Cultures from August and September were primarily affiliated with the genera *Limnohabitans*, *Flavobacterium*, and *Polynucleobacter*, while those from October were dominated by members of the genus *Verrucomicrobium*.

Two of the isolated bacteria, affiliated with the ubiquitous genus *Polynucleobacter*, were selected for phage isolation. For phage enrichment and isolation water collected from the lake was pre-filtered through a 42 µm mesh on-site to remove larger plankton, then further filtered through a 0.1 µm filter in the lab to obtain a phage-containing flowthrough. This flowthrough was added to mid-exponential phase *Polynucleobacter* cultures to introduce phages. Phage infection was screened using flow cytometry comparing infected and control treatments. We use this phage-host system to perform gene resolved differential transcription analyses along the phage infection cycle to resolve the infection strategies and molecular mechanisms of freshwater phage–host interactions

Plasmid recombination: a key strategy for understanding the dynamics of plasmids and antibiotic resistance in bacteria

Acacia E¹, Tuffet R¹, Charpentier X³, Bruto M⁴, Rousseau P², Venner S¹, Koffel T¹

¹LBBE, ²LMGM, ³CIRI, ⁴VetAgro Sup, Anses, UMR Mycoplasmoses animales

POSTER SESSION 1 - **P01.131**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Antibiotic resistance (AR) is one of the greatest threats for public health. AR genes widely circulate through genetic exchange between bacterial individuals, mainly by being carried by mobile genetic elements such as plasmids. Because of their mobility between bacterial cells, plasmids can be seen as genetic entities with their own evolutionary trajectory, partly independent of that of their host. To understand AR gene dynamics, it is therefore essential to study the eco-evolutionary dynamics of plasmids. The two plasmid strategies mainly studied are their capacity for transmission either horizontal (from one cell to another, independently of their replication) or vertical, (from replication, and facilitated by the carriage of accessory genes (e.g. the AR gene) that may be beneficial to their host). However, these approaches consider plasmids as stable genetic entities, whereas there is growing evidence that they can shuffle genes when they coinfect the same bacterial cell. In our study, we will therefore consider the evolution of a new plasmid trait, that of their recombination rate. Based on a theoretical modelling approach, we propose to test the hypothesis that genetic shuffling may increase plasmid flexibility and enable them to cope with environmental fluctuations.

By transposing host-pathogen models from epidemiology, we developed a dynamical model of plasmids transferring horizontally and vertically within a bacterial population. The model is multiscale, with (i) AR genes that are carried by plasmid (ii) plasmids that belong to a given recombining family (iii) and bacteria competing for a limited resource in a population exposed to a fluctuating environment (antibiotic stresses). When two related plasmids (i.e. belonging to the same

family) coinfect the same bacterial cell, they would exchange genes with a given recombination rate, which represents the family strategy.

Our results show that over a very wide range of conditions tested, an intermediate recombination rate optimally buffers environmental fluctuations, enabling the genotype adapted to the current condition to be generated rapidly. There is a balance between getting rid of AR genes when there is no stress, but not too fast so that they can be remobilized rapidly when needed under antibiotic stress. An intermediate recombination rate confers a selective advantage by maintaining a diversity of plasmid genotypes, including those that are not adapted to current conditions, and are maintained at low densities but are likely to re-emerge when they become the most advantageous again (for example, during a period of stress). In this sense, our work shows that the spread of AR genes is highly dependent on plasmid recombination rate strategies.

The predictions of our models echo the growing body of work showing that the plasmids that pose a public health problem are extremely flexible and can mix genes at a not negligible rate when they coinfect the same bacterial cell. Our result suggest that the spread of AR genes is a matter of interaction between plasmids (or more largely mobile genetic elements), themselves and between plasmids and their bacterial host, alternating with conflict and cooperation. Mathematical modeling of plasmid evolutionary strategies combined with genomic analysis may constitute a powerful tool to disentangle these complex evolutionary interactions.

Purifying Selection Shapes the Dynamics of P-element Invasion in *Drosophila simulans* Populations

Langmüller A^{1,2,3,4}, Haller B³, Nolte V², Schlötterer C²

¹Vienna Graduate School of Population Genetics, ²Institut für Populationsgenetik, Vetmeduni Vienna,

³Department of Computational Biology, Cornell, ⁴AIAS, Aarhus University

POSTER SESSION 1 - P01.123, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements (TEs) are DNA sequences that can move within a host genome. Many new TE insertions have deleterious effects on their host and are therefore removed by purifying selection. The genomic distribution of TEs thus reflects a balance between new insertions and purifying selection. However, the inference of purifying selection against deleterious TE insertions from the patterns observed in natural populations is challenged by the confounding effects of demographic events, such as population bottlenecks and migration.

We used Experimental Evolution to study the role of purifying selection during the invasion of the P-element, a highly invasive TE, in replicated *Drosophila simulans* populations under controlled laboratory conditions. Because the change in P-element copy number over time provides information about the transposition rate and the effect of purifying selection, we repeatedly

sequenced the experimental populations to study the P-element invasion dynamics. Based on the empirical data, we used Gaussian Process surrogate models to efficiently explore the parameter space and identify parameter combinations that best reproduce the experimental P-element invasion trajectories. Assuming that beneficial P-element insertions are negligible, we found that, in our experimental populations, 73% of new P-element insertions are under purifying selection with a mean selection coefficient of -0.056, highlighting the central role of selection in shaping P-element invasion dynamics.

This study underscores the power of Experimental Evolution as a tool for studying transposable element invasions, and highlights the pivotal role of purifying selection in regulating P-element dynamics. Furthermore, it also illustrates how computational modeling can complement experimental work to study TE invasions.

Repeatome analysis in an Amazonian riparian forest ground-herb reveal potential role of LTR-Retrotransposons on waterlogging adaptation mechanisms

Canal D¹, Canal D¹, Mortati A², André T², Palma-silva C¹

¹State University Of Campinas, ²University of Brasília

POSTER SESSION 1 - **P01.134**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The highly dynamic nature of riparian forests has led to a remarkable adaptability of the ground herb *Ischnosiphon puberulus* to a flooding gradient. Through an integrated genomic and transcriptomic approach, we uncovered the molecular basis of stress response of *Ischnosiphon puberulus* to thrive extreme flooding variability (from Igapo to Terra firme). This scenario of contrasting environmental conditions makes *I. puberulus* an ideal model for investigating the genomic bases of adaptive mechanisms in response to climate change. Long Terminal Repeat Retrotransposons (LTR-RTs) usually represent the most abundant fraction of plant genomes, mostly due to their replicative process, in which copies of active elements are constantly inserted into new genomic locations. The activity of LTR-RTs has the potential to generate genomic diversity by causing structural variation and/or impacting gene regulation and their continuing study has provided numerous insights into their role in shaping mechanisms of stress-related adaptation. Here, we aim to investigate the impact of LTR-RTs on the mechanisms of local adaptation of *Ischnosiphon puberulus* populations in a flooding gradient. To this end, we first used the reference *I. puberulus* genome, previously published by our research group, to annotate the LTR-RT elements at the lineage level using the DANTE_LTR pipeline. This analysis revealed that 29% of the *I. puberulus* genome is composed of LTR-RTs, with 4.4% belonging to the Ty1/copia superfamily and 23.8% to the Ty3/gypsy superfamily. The chromovirus Tekay (Ty3/gypsy) was by far the most abundant LTR-RT, accounting for 20.6% of the genome. We then used the TE-Density pipeline to estimate the average density of five major lineages of LTR-RTs (Ty1/copia-lvana, Ty1/copia-lkeros, Ty1/copia-Tork, Ty3/gypsy/chromovirus-CRM, and the

previously mentioned Ty3/gypsy/chromovirus-Tekay) that were located within and 10 kb (500 bp windows) upstream and downstream of *I. puberulus* annotated genes. The results showed an overall low average density of LTR-RTs within and in close proximity to genes, with increasing densities toward the 10 kb upstream and downstream regions. We also investigated LTR-RT density using the same parameters in a subset of stress-related genes. Previous work from our group identified expanded cytochrome P450 (CYP) transcripts with distinct expression profiles in populations under different flooding conditions. These enzymes are crucial for processes such as secondary metabolite biosynthesis, hormone metabolism, and stress resistance. The average LTR-RT density upstream of this subset of genes was up to five-fold higher than the average for the complete gene set, with no clear pattern throughout the 10 kb visualized region. The significantly different pattern of LTR-RT density in these important genes suggests that LTR-RTs may be involved in the expansion and/or regulation of stress-related genes, either by transposing additional copies or by affecting promoter/enhancer activity. Preliminary results showed that 20.5% of the identified LTR-RTs possessed intact target site duplications and primer binding sites, which are features indicating potentially active elements. As LTR-RT activity may still be shaping adaptive processes in *I. puberulus*, our next step is to use our available RNA-Seq data to evaluate which of these LTR-RTs are transcriptionally active and whether their expression differs among a sampling of 41 individuals across a flooding gradient. This expression data can then be integrated with our LTR-RT density results to assess whether LTR-RT activity is occurring near genes of interest and potentially contributing to adaptive responses on a genomic level.

Role of AluYRa1 insertion in Generating a New Isoform of the BHMT Gene in Old World Monkeys

Lee Y^{1,2}, Choe S¹, Cho H¹, Park H^{1,2}, Ko M^{1,2}, Park S¹, Kim Y¹, Huh J^{1,2}

POSTER SESSION 1 - **P01.119**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background Transposable elements (TEs) make up approximately 55% of the human genome and are divided into retrotransposons and DNA transposons based on their mechanism of mobilization—copy-and-paste and cut-and-paste, respectively. These elements contribute to genome evolution and plasticity, often influencing gene regulation and alternative splicing (AS) by inserting novel splice sites. In our previous study, we identified a novel isoform of the BHMT gene in cynomolgus macaques containing an exon derived from AluYRa1 and Tigger 4 elements. This study explores the origin, insertion mechanisms, and evolutionary relevance of this isoform in primates.

Materials and Methods We examined BHMT gene structures in 18 primate species using NCBI and UCSC genome databases. Genomic PCR was performed on DNA samples from seven species to detect TE insertions, while in-silico PCR was applied to 11 additional species to trace evolutionary insertion events. To confirm the expression of the novel isoform, RT-PCR was conducted using total RNA from 10 tissues of cynomolgus macaques. Splice site prediction and sequence alignment were used to identify exonization patterns and truncations.

Results The canonical BHMT gene comprises 8 exons and 7 introns in most primates, except in gorillas, where a ninth exon is observed. In Old World Monkeys (OWMs), we identified that AluYRa1 retrotransposed into

a pre-existing Tigger 4 element between exons 7 and 8 via a target-primed reverse transcription (TPRT) mechanism. AluYRa1 provides a novel 3' splice site and Tigger 4 serves as a 5' splice site, enabling the formation of a new exon through exonization. RT-PCR analysis confirmed that this variant isoform is expressed in the cerebrum, heart, kidney, liver, and stomach. In-silico PCR revealed that a second AluYRa1 insertion, located upstream of the first, exists in four species. However, this second element underwent 3' truncation, likely due to incomplete TPRT. A short poly-T tail was observed following the target site duplication (TSD), indicating the presence of a poly-A tail in the RNA intermediate during Alu retrotransposition. Furthermore, four OWM species exhibit a ~40 bp deletion at the 3' end of AluYRa1, disrupting the splicing signal and preventing isoform formation.

Conclusion Our findings demonstrate that the combination of AluYRa1 and Tigger 4 elements can create novel splice sites that promote exonization and contribute to alternative splicing in a lineage-specific manner. These events are restricted to OWMs, as the AluYRa1 insertion is absent in great apes and New World monkeys. The observed truncation and deletion events further illustrate how subtle sequence changes in TEs can influence gene isoform evolution. This study underscores the significant role of TEs in generating transcriptomic diversity during primate evolution.

Sequence composition and conservation predict the phenotypic relevance of transposable elements

POSTER SESSION 1 - P01.125, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements (TEs) are powerful drivers of genome evolution, in part through their ability to rapidly rewire the host regulatory network by creating transcription factor binding sites that can potentially be turned to the host's advantage in a process called exaptation. However, the effects on the host phenotype vary widely among different TEs, and are in general poorly understood. In this work, we have classified human-mapping TEs based on their contribution to the human host phenotypes at both molecular and macroscopic scales. TE contributions to chromatin accessibility, gene expression, and the heritability of complex traits are strongly correlated to each other, confirming that the main mechanism through which TEs affect the host phenotype is through the rewiring of the regulatory network. TE sequence characteristics and evolutionary features are able to explain a large fraction of the variance in phenotypic relevance, and in particular

more than 50% of the variance of their contribution to the heritability of complex traits. A conspicuous exception to this pattern is represented by TEs of the ERV1 family, whose phenotypic impact cannot be explained by our models: In particular, this family includes a set of relatively young TEs whose phenotypic relevance is much larger than would be expected based on their sequence and evolutionary parameters. These TEs are involved in fast-evolving biological processes related to the interaction of the organism with its environment, a role that could in part explain their deviation from our models. In conclusion, our results confirm quantitatively that TE insertions affect the host phenotype mostly through the rewiring of its regulatory network; identify a signature of phenotypic relevance based on sequence and conservation properties; and highlight several TEs as promising candidates for functional studies.

Stealth plasmids: rapid evolution of deleted plasmids can displace antibiotic resistance plasmids under selection for horizontal transmission

Matthews A², **Dimitriu T**¹

¹University of St Andrews, ²University of Exeter

*POSTER SESSION 1 - **P01.133**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Conjugative plasmids carrying antimicrobial resistance (AMR) genes are critical for the spread of AMR, due to their ability to transmit horizontally between bacterial hosts. We previously observed that during experimental evolution in the presence of abundant susceptible hosts, the AMR plasmid R1 rapidly evolves variants with increased horizontal transmission due to mutations causing increased plasmid copy number. Yet AMR was progressively lost from the evolving populations. Here, we show that AMR loss was associated with evolution of 'stealth' plasmids in which the AMR region is

spontaneously deleted, making plasmid carriage undetectable by plating on selective antibiotic-containing media. These plasmids transmit both vertically and horizontally more efficiently than the ancestral AMR plasmid, driving AMR extinction in bacterial populations and effectively acting as an intrinsic defence against AMR plasmids. Our results suggest that within-host plasmid evolution could be exploited to limit the spread of AMR in natural populations of bacteria.

The co-evolutionary dynamics of CRISPR-Cas and plasmids

Losa Mediavilla C², Chabas H², Kouyos R¹, Bonhoeffer S², **Siedentop B**^{1,2}

¹University Hospital Zurich And University Of Zurich, ²ETH Zürich

POSTER SESSION 1 - P01.136, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

CRISPR-Cas is an adaptive immune system that protects bacteria from virulent phages. Upon infection, CRISPR-Cas acquires memory against foreign invaders by storing spacers, which are sequences derived from invaders and are later used to recognize and degrade them. On a molecular level, CRISPR-Cas is also active against plasmids, important drivers of bacterial evolution. However, the impact of CRISPR-Cas on the ecology and evolution of plasmids is less understood compared to the well-studied interaction between CRISPR-Cas and phages.

Unlike phages, plasmids can be either beneficial or costly for their bacterial host. While some evidence suggests that CRISPR-Cas might allow the spread of beneficial plasmids, the interaction of costly plasmids and CRISPR-Cas is more complex. A simple mathematical model predicts that CRISPR-Cas can block the spread of costly plasmids. However, several escape mechanisms, such as anti-defense systems, enable costly plasmids to persist in bacterial populations despite CRISPR-Cas immunity.

For phages, it is well established that not only anti-defense systems but also escape mutations in immune targets allow CRISPR-Cas evasion. The role of escape mutations in maintaining costly plasmids under CRISPR-

Cas pressure is unclear. To investigate whether plasmid mutations promote persistence of costly plasmids in the presence of CRISPR-Cas we use mathematical modelling. Our stochastic model focuses on the early phase of plasmid and CRISPR-Cas co-evolution, where each CRISPR-Cas system carries at most one spacer. In the case of phages, this initial phase of co-evolution is known to often drive phages to extinction through population-wider spacer diversity.

While our preliminary results suggest that escape mutations might allow costly plasmids to persist through the initial co-evolutionary arms race between CRISPR-Cas and plasmids, this outcome may depend strongly on the effect the escape mutations have on plasmid fitness. CRISPR-Cas spacers often target plasmid backbone genes, which are likely harder to escape without affecting plasmid fitness. So far, we assumed in our simulations that escape mutations increase plasmid cost. By incorporating varying fitness effects of escape mutations including their impact on other plasmid parameters such as plasmid conjugation, our mathematical model will improve the understanding of the co-evolution between CRISPR-Cas and plasmids and the impact CRISPR-Cas has on plasmid spread.

The latent cis-regulatory potential of mobile DNA in Escherichia coli

Fuqua T^{1,2}, Wagner A^{1,2,3}

POSTER SESSION 1 - P01.124, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements can alter gene regulation in their host genome, either when they integrate into a genome, or when they accrue mutations after integration. However, the extent to which transposons can alter gene expression, as well as the necessary mutational steps, are not well characterized. Here we study the gene regulatory potential of the prominent IS3 family of transposable elements in E.coli. We started with 10 sequences from the ends of 5 IS3 sequences, created 18,537 random mutations in them, and measured their promoter activity using a massively parallel reporter assay. All 10 sequences could evolve de-novo promoter activity from single

point mutations. De-novo promoters mostly emerge from existing proto-promoter sequences when mutations create new -10 boxes downstream of preexisting -35 boxes. The ends of IS3s harbor ~1.5 times as many such proto-promoter sequences than the E. coli genome. We also estimate that at least 26% of the 706 characterized IS3s already encode promoters. Our study shows that transposable elements can have a high latent cis-regulatory potential. Our observations can help to explain why mobile DNA may persist in prokaryotic genomes. They also underline the potential use of transposable elements as a substrate for evolving new gene expression.

Towards building a global atlas of microbial Mobile Genetic Elements

POSTER SESSION 1 - P01.130, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The metagenomics revolution revealed the ubiquity of microbes across all known ecosystems on earth. It provided the methods to study taxonomic and functional microbial diversity. However, we still lack understanding about how microbes adapt and survive across the diverse habitats of our planet. As methods to study microbial adaptability fueled by horizontal gene transfer of molecular functions are limited. To address this, we focused on the identification of the drivers of horizontal gene transfer in microbes and microbial communities, the Mobile Genetic Elements (MGE) namely IS elements, transposons, phages, conjugative elements. By addressing a methodological gap in the field for simultaneous identification of different MGE types and their interactions at a go, we made complete MGE profiles of environmental microbial (meta)genomes accessible. Our knowledge-based framework used combination of universal marker gene-based approach and

pangenome information to identify >23 million MGEs across ~800k complete genomes and ~200k Metagenome Assembled Genomes from diverse host-associated and environmental habitats represented in public datasets. We identified MGE interactions represented by >4 million nested elements, and observed recent horizontal spread of full length MGEs transcending the prokaryotic tree of life. Despite the presence of strong MGE type specific genomic signatures, we found certain molecular functions promiscuously carried as cargo by different types of MGEs. Thus, we present a modular, scalable and adaptable computational framework that enables high resolution comparative investigations of MGEs, their interactions, cargo functions and horizontal spread at planetary scale. Our framework builds the foundations for addressing the knowledge gap of the role of MGE mediated horizontal spread in shaping microbial communities of our planet.

Transposable element mobilization in the soma of hypomethylated *Arabidopsis thaliana*

Movilli A¹, Sushko S¹, Rabanal F¹, Weigel D¹

¹Max Planck Institute For Biology Tübingen

POSTER SESSION 1 - **P01.128**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Transposable elements (TEs) are potent drivers of genome evolution through their capacity to induce heritable genetic changes. In animals, early germline specification limits the opportunity for somatic TE mobilizations to contribute to heritable variation. In contrast, plants exhibit a more plastic and late specification of the germline, allowing somatic TE insertions, although rare, to potentially enter the germline and be inherited.

Prior studies in *Arabidopsis thaliana* have largely centered on TE mobilization in the germline of DNA hypomethylation mutants and somatic transpositions remain largely underexplored.

Here, we used high-accuracy PacBio HiFi long-read sequencing to investigate somatic TE activity in individual plants of a non-

reference *A. thaliana* strain lacking METHYLTRANSFERASE1 (MET1), a key enzyme in DNA methylation maintenance. We found that most mobile TE families overlapped with those previously identified in germline-focused studies, yet mobilization often involved distinct element copies. Our approach also uncovered active TEs absent from standard annotations. Somatic TE activity varied between individuals and across TE families. Notably, we identified signatures of alternative transposition involving two closely spaced Mutator-like elements, suggesting a potential mechanism underlying localized genomic instability.

These findings highlight somatic TE mobility as a powerful, rapid readout for studying TE behavior at single-organism resolution and offer new insights into the genomic consequences of epigenetic deregulation.

Unveiling Hidden Phage Diversity: Addressing Assembly and Identification Biases in Metagenomic Analyses of Mutation Hotspots

Silva Kavagutti V¹, Mehrshad M¹

¹Swedish University of Agricultural Sciences – SLU

POSTER SESSION 1 - **P01.127**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Standard metagenome assembly pipelines often struggle to recover repetitive, small, highly diverse, or rapidly evolving sequences. This leads to fragmentation of the assembly and can lead to underrepresentation of genomic regions important for phage evolution and host interaction. In this study, we explore how tracing identified viral contigs in assembly graphs and identifying assembly bubbles can help uncover hidden viral diversity typically missed in metagenomic studies of virus diversity.

In this study, we analyzed eleven publicly available metagenomic datasets from Lake Erken, Sweden, to evaluate the extent of viral sequence recovery across successive rounds of assembly. Each dataset was assembled using MEGAHIT. Metagenomic reads were mapped against assembled contigs larger than 2 kb. The unmapped metagenomic reads were extracted, normalized with bbnorm, and reassembled. This process was repeated 2 times. The first round of assembly produced over 446,000 contigs (2–329 kb size range), and an additional 17,900 (2–8 kb size range) and 378 (2–3.4 kb size range) contigs were recovered in the second and third assembly rounds, respectively.

Viral contigs were identified using a combination of geNomad, VIBRANT, and PPR-meta. Within all assembled contigs, 65,286 contigs with an overall size of 285 mb were identified as viral. These viral candidates were then traced to their corresponding positions in assembly graphs to detect structural patterns such as bubbles and super bubbles. We recovered 13,562 graphs containing at least two viral nodes. These virus-affiliated assembly networks had a total size of 855.19 mb, from which only ~20% (175.75 mb) was identified as viral sequences using state-of-the-art virus identification tools. Observed graph structures suggest the presence of complex sequence variation, which is relevant to population diversity, pangenome-level organization, and host interaction.

We aim to further investigate how such graph features relate to mutation hotspots and strain variation, particularly in genomic regions often fragmented or excluded in metagenome assemblies. If successful, this approach could offer a scalable workflow to enhance viral genome recovery and improve identification strategies in complex microbial communities

A phage protein evolved to limit satellite phage induction and mobilization

Morency C¹, Rousseau G¹, Morneau Z¹, Moineau S¹

¹Université Laval

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Streptococcus thermophilus is one of the most widely used lactic acid bacteria in the production of various cheeses and yogurts. However, even if carefully selected, industrial strains can be infected by virulent phages naturally present in milk, leading to lower-quality fermented products. Developing tools that harness different phage resistance mechanisms could help reduce production losses and associated costs. *S. thermophilus* relies heavily on the CRISPR-Cas system to defend itself against phage infections. Nevertheless, some phages have evolved strategies to bypass this defense, such as producing anti-CRISPR (ACR) proteins that bind directly to Cas9 and deactivate the system. The overall aim of this study is to identify alternative natural methods to enhance phage resistance in *S. thermophilus*, since the use of genetically engineered organisms is generally viewed negatively by consumers.

Mobile genetic elements (MGEs) play a crucial role in bacterial evolution by expanding the gene pool within bacterial populations. Satellite phages are a distinct subset of MGEs, found integrated into the genomes of various bacterial species, including *Staphylococcus aureus*, *Escherichia coli*, and *Vibrio cholerae*. Previous studies have shown that specific satellite phages in *S. aureus*, known as SaPIs, can interfere with the replication of certain temperate phages. In our analyses, we observed structurally similar satellite phages in the genome of 69% *S. thermophilus* strains. This high prevalence suggests that satellite phages may provide a selective advantage to *S. thermophilus*, a species known to harbor few or no prophage.

We recently showed that some *S. thermophilus* satellite phages (StCIs) can spontaneously excised and circularized from the bacterial chromosome as detected in overnight culture using PCR with primers targeting both ends of the StCI. Through CRISPR-Cas9 interference, we were also able to cure some *S. thermophilus* cells of StCI. Using these StCI-free strains, we successfully mobilized StCIs from one *S. thermophilus* strain to another via natural competence (ability to take up DNA from its environment). Of note, we found that exchanging specific StCIs enhance the overall phage resistance of the recipient strain. Here, we further investigated the phage resistance phenotype conferred by acquiring a new StCI.

We first isolated virulent phage mutants capable of bypassing the resistance phenotype. Genome analysis identified a single nucleotide mutation that led to an amino acid substitution in a DNA-binding protein. We also found that the wild-type phage DNA-binding protein was able to trigger StCI induction, while the mutated version could not. Further analysis revealed that this mutation imposed a fitness cost on the virulent phage, as evidenced by smaller plaque sizes compared to the wild-type. Finally, we demonstrated that StCI induction by a virulent phage enhances its mobilization via natural competence. However, this mobilization was almost entirely abolished in the presence of the phage mutant. Taken together, our findings highlight the rapid evolutionary adaptation of virulent phages to the StCI resistance mechanism. While the mutated phage protein prevented StCI induction and reduced its mobilization through natural competence, it did so at the cost of phage fitness.

A selective bottleneck during host entry drives the evolution of new plant symbionts

⁴Evolution et Diversité Biologique, UMR5174, CNRS-Université Paul Sabatier

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

The acquisition of mobile genetic elements (MGEs) can trigger radical shifts in microbial lifestyles, for example by converting a mutualist into a pathogen or vice versa. These transitions often involve changes in host range, infection strategies, or ecological niches, which typically require specific adaptations to the different stages of the new life cycle. While comparative genomic studies have documented several MGE-associated lifestyle transitions, a detailed understanding of the tempo and mode of adaptation to new symbiotic lifestyles is still lacking.

Here, we sought to evolve new nitrogen-fixing bacterial symbionts of the legume plant *Mimosa pudica* from an ancestral plant pathogenic bacterium, *Ralstonia solanacearum*, which was engineered with a plasmid carrying essential symbiosis genes. We experimentally evolved this strain for over 900 generations during serial passages through a simplified symbiotic life cycle (comprising rhizosphere inoculation, root entry, and within-plant proliferation) and

characterized the dynamics of molecular and phenotypic adaptation in the evolved populations.

Multiple independent lineages exhibited rapid and parallel fitness increase during their interaction with *M. pudica*. Whole-population sequencing revealed a continuous accumulation of mutations, facilitated by a plasmid-induced transient hypermutagenesis phase before host entry. We observed sequential sweeps of mutational cohorts, with multiple adaptive mutations co-occurring within these cohorts. Notably, all adaptive mutations enhanced host entry, while only a subset also improved within-host proliferation. Computational modelling suggests that this pattern is a consequence of the strong selective bottleneck occurring at host entry and immediately following the hypermutagenesis phase. Our findings highlight how selective bottlenecks shape adaptive trajectories of symbiotic bacteria experiencing complex infection processes.

Bacterial warfare plasmids are associated with virulence and antimicrobial resistance

Sharp C¹, Foster K²

¹University Of Reading, ²University of Oxford

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Bacteria have evolved diverse weapons to kill or inhibit competitors. These weapons are often encoded on large mobile genetic elements that encode additional genes and functions. However, how these mobile genetic elements evolve and their impacts on the ecology and evolution of bacterial communities remains poorly understood. Here we explore this question using the bacteriocins of *E. coli*, which are both well studied and have large well-annotated genomic resources. While bacteriocins are found widely across *E. coli* strains, we find that carriage is particularly associated with pathogenic extra-intestinal (ExPEC) lineages, including many clinically-important pandemic strains. These pathogenic strains commonly carry large plasmids that encode the bacteriocins but also virulence factors, including siderophores, and antimicrobial resistance mechanisms. Notably, combinations of siderophores and

bacteriocins targeting siderophore receptors have evolved independently multiple times and are maintained in certain lineages, likely enhancing bacterial survival in complex environments like the inflamed human microbiome. Across all *E. coli* strains, we identify numerous orphan immunity proteins, suggesting that bacteriocin-mediated warfare plays a key role in shaping microbial communities. We also present evidence for frequent horizontal transfer of bacteriocin genes between strains via plasmids and between plasmids via transposons. Finally, several *E. coli* bacteriocins are shared with *Salmonella enterica*, reinforcing their link to virulence. Our findings highlight the role of *E. coli* bacteriocins in defining bacterial communities and as potent antibacterial weapons in antimicrobial-resistant pathogens.

Evolutionary dynamics of phage domestication across prokaryotes

Le Cras Y^{1,2}, Rocha E¹

¹Institut Pasteur, Université Paris Cité, CNRS, UMR3525, Microbial Evolutionary Genomics, ²Ecole doctorale n°515, Complexité du vivant, Sorbonne Université, Collège doctoral

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Mobile genetic elements (MGEs) drive multiple functional innovations within microorganisms. Notably, it has been hypothesized that prophages were domesticated into contractile secretion systems driving inter-bacterial warfare, such as the Type VI secretion systems (T6SS). We setup to identify the complex processes of phage co-option and functional innovation leading to domesticated contractile systems across the available diversity of complete prokaryotic genomes.

To construct our dataset, we integrated different methods using sequence and structural similarity to search for distant homologs of experimentally characterized systems (tailocins, external contractile injection systems, T6SS). We detected more than 20,000 systems and related phages across bacteria and archaea, redefining their distribution. To reconstruct their most probable path of evolution, we build phylogenetic trees using a variety of

techniques with tree search based on sequences (maximum likelihood and Bayesian sampling) or structures. Our results show that contractile systems have been co-opted from phages numerous times, particularly in the case of tailocins. We refined the phylogenies of each systems clade and identified common aspects between independent paths of prophage domestication.

These results shed light on the long-term evolutionary impact of MGEs in prokaryotes. Of note, contractile injection systems enhancing host fitness by antagonising microbial competitors are sometimes encoded in MGEs and thus transferred across bacteria and archaea. Together, these results underline the importance of mobile genetic elements in microbial interactions. On one hand they promote functional innovations, on the other hand they spread these innovations across microbial lineages.

Genetic exchange networks bridge mobile DNA vehicles in the bacterial pathogen *Listeria monocytogenes*

Andam C¹

¹University At Albany, State Univ Of New York

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Background: *Listeria monocytogenes* (Lm) is an opportunistic foodborne pathogen responsible for gastrointestinal illnesses and life-threatening invasive infections. Antimicrobial resistance, virulence, and the ability to rapidly adapt to stressful environments in Lm lie in part on its mobile genetic elements (MGE).

Materials and methods: Here, we aim to characterize the MGE pool of a clinical Lm population using 936 genomes sampled across New York State, USA. We built a network based on sequence homology among putative MGEs.

Results: Within the network are communities of densely interconnected MGEs indicating high genetic similarity in their DNA regions. Although most connections involve the same MGE type, subsets within the network link different MGE types (plasmid-transposon, phage-plasmid). Phages and transposons did not share any genetic connections, suggesting impermeable barriers of exchange between them. Genes involved in stress tolerance are overrepresented in plasmids and transposons, and are mobile between vehicles. Analysis of long-read sequences of a subset of our dataset (n=37)

and publicly available, globally distributed complete genomes (n=425) recapitulated the MGE connections we observed. Our findings reveal a structured but interconnected network of genetic exchanges between different mobile DNA vehicles.

Conclusions: The impact of genetic exchanges among MGEs is threefold: (i) large variation in genetic content among distinct co-circulating lineages; (ii) adaptive potential that can be rapidly disseminated at short evolutionary timescales; and (iii) genetic mosaicism of DNA vehicles that lead to the confluence of traits, especially those relevant to human health and disease. Altogether, our findings add an extra layer of complexity in the forces governing HGT in Lm that extend beyond the transfer between donor and recipient cells. More generally, mosaicism in MGE illustrates the interconnected evolutionary histories of a priori distinct entities. Our work provides a portrait of the standing diversity of MGEs in clinical Lm, which is useful in understanding the bacterial genetic and evolutionary features that make Lm a highly resilient and persistent pathogen in various environments.

Into the Evolutionary Arms Race: Role of Mobile Genetic Elements in Giant Viruses

Sánchez L¹, Bisio H², Willemssen A¹

¹University of Vienna, Centre for Microbiology and Environmental Systems Science, Division of Microbial Ecology, ²Aix-Marseille Université, CN de la Recherche Scientifique, Information Génomique & Structurale

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Eukaryotic giant viruses are a highly diverse group of recently discovered viruses classified within the phylum Nucleocytoviricota. They exhibit remarkably large genome sizes, believed to result from gene duplication and horizontal gene transfer facilitated by genetic exchange among eukaryotic hosts, viruses, and bacterial endosymbionts. Giant viruses also harbor prokaryotic-like mobile genetic elements (MGEs), such as group I introns and inteins associated with homing endonuclease domains, which promote MGE mobility and genome evolution. Although MGEs have been identified in giant viruses, their specific roles remain unexplored. Here, we investigate whether MGEs confer fitness advantages to giant viruses during co-infections within amoeba host cells. Using homologous

recombination, successive knockout mutants of MGEs in *Acanthamoeba polyphaga* mimivirus (APMV) have been generated. The impact of these deletions on viral fitness and competitive ability was assessed by comparing the replication success of mutant and wild-type viruses, as well as by visualizing the cellular localization of competing viruses via fluorescence microscopy. Preliminary results show a significant decrease in the fitness of the knockout mutant in presence of the wild-type virus, suggesting that the MGE confers a competitive advantage. This research aims to elucidate the role of MGEs in the evolutionary arms race among giant viruses, other parasites, and their hosts, thereby advancing our understanding of ecological dynamics within host-associated microbial communities.

Rapid genetic differentiation across short geographic scales in firefly *Photinus pyralis*

Rogers R¹

¹Unc Charlotte

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

North American fireflies have experienced recent shifts in selective pressures due to human encroachment, habitat destruction, pesticide use, and light pollution. The ability of organisms to adapt to these environmental shifts depends directly on the substrate of mutations available to serve as targets of selection. Different mechanisms of mutations, duplications, TE movement, rearrangements or SNPs, appear at different rate with differing impacts on selective coefficients. If evolution is limited by mutation, then targets of selection will be constrained to standing genetic variation. However, if mutations appear rapidly, then organisms can adapt more freely with adaptive solutions from new mutation. We have identified two populations of fireflies *Photinus pyralis* in close proximity less than 11km apart with phenotypic differences in light signal color. We use a whole genome population genetic approach to identify targets of selection that also show strong differentiation across populations beyond

neutral expectations. Genes at signatures of adaptive differentiation include eye development genes, pigment processing pathways, and pesticide resistance loci. Both SNPs and tandem duplications appear to be mutation limited, with over 95% of targets of selection coming from standing genetic variation shared across populations. However, 35-40% of adaptive TE movement and rearrangements are derived from new mutations. These results indicate that transposable elements and rearrangements rapidly remodel genomes and fortuitously contribute to adaptive changes on short timescales. Our results suggest that TEs offer one mechanism to circumvent mutational constraints during adaptive walks resulting in rapid evolutionary change. These mutational mechanisms appear to be an important component of adaptation in fireflies deserving greater attention in the emerging field of non-model population genomics.

Too Hot to Keep, Too Cool to Skip: The influence of thermal environment on the diversity of transposable elements in Polychaets

MEETING ROOM 122+123, August 18, 2025, 2:00 PM - 5:00 PM

Genome evolution plays a central role in enabling organisms to adapt to ever-changing environments, especially in the context of global environmental change. Among the primary drivers of genetic plasticity are transposable elements (TEs), which can induce various mutations as repeated and mobile sequences. To persist in genomes, TEs have evolved diverse strategies to evade host repression. One well-described mechanism is stress-induced transposition, whereby biotic or abiotic stresses trigger TE activation, leading to new insertion events. This makes TEs essential players in the adaptive response. Temperature, as an abiotic factor, is known to influence TE activity. In this study, we examine the role of thermal environments in shaping TE diversity at a macroevolutionary scale, using marine polychaete annelids as a model system. These mainly benthic organisms occupy a wide range of thermal habitats, from polar waters to hydrothermal vents and temperate coasts. They provide a unique opportunity to investigate the effects of temperature on genome evolution through a comparative genetic analysis. TE diversity varied substantially among polychaete species, with significantly lower diversity in

species exposed to extreme and unstable temperatures, associated with hydrothermal vents. Indeed, the diversity of most TE types was significantly reduced in such environments, while it was higher in thermally stable habitats. Only the diversity of tyrosine recombinase (YR) retrotransposons appeared to be more influenced by phylogenetic lineage, showing lower diversity in Sedentaria, though also affected by the thermal environment. Finally, phylogenetically informed analyses confirmed that both lineage and thermal environment shape overall TE diversity. Our results suggest a host response to the overall TE load—heavier in thermally unstable environments—rather than a TE-specific dynamic linked to temperature. In unstable environments, a high mutation rate induced by transposition may drive purging of TE diversity to maintain genome integrity. In contrast, species in stable environments retain diverse TE families, possibly preserving adaptive potential for future stress. These findings highlight long-term eco-evolutionary dynamics governing TE-host interactions and the role of the thermal environment in genome evolution.

Do artificial intelligence tools help students with their evolutionary ecology homework? And are they willing to disclose it?

Rutkowska J Institute of Environmental Sciences, Faculty of Biology

POSTER SESSION 2 – P02.025, EXPO AREA, August 19, 2025, 5:00 PM – 7:00 PM

Background: Unanimous access to artificial intelligence (AI) tools is an opportunity for ease of work and creativity. Researchers and students use them. Are students using them effectively? Are they ready to disclose their use? So far, the first of those questions has not been addressed in the case of university students.

Materials and methods: Here, I used data from homework assignments in the Evolutionary Ecology course taught to MSc students over five years (2020-21 and 2023-2025), with the last three years characterized by the availability of AI tools. In 2025, an optional declaration of AI use was added to the assignments. In each year there were between 10 and 31 students, and here I have analysed over 250 of their assignments. In subsequent years, some homework assignments had the same content but different numerical values. In each case, the specific aspect of the homework can be rated as correct/incorrect. These are 1. estimating the population size required to detect inbreeding, 2. calculating the inclusive fitness of individuals helping their kin to reproduce, 3. determining the proportion of individuals at which the population could reach the mean maximum

fitness, 4. assessing the interaction term in a 2x2 factor simulation of the persistence of the metapopulation system.

Results: I found that the probability of correct answers was higher in two tasks and lower in two others before and after the introduction of AI tools. The reported use of AI tools varied widely across the four assignments, indicating that students do not use AI "by default" but rather when they feel the need. However, at the individual level, there was no relationship between correct answers and reported use of AI.

Conclusions: These results may indicate that students did not understand the nature of the questions or were unable to effectively prompt the AI for correct answers. It is less likely that the tasks were inherently resistant to AI assistance. Either way, these findings may be useful for other teachers of evolutionary ecology. Irrespective of the merits of the tasks, I was pleased to see that the majority of the students, when given the opportunity, filled in the questionnaire regardless of whether they reported using AI or not. This confirms previous findings that students are willing to use AI in an open and professional manner.

From predation to mutualism: authors' gender identities influence the focus of ecological research on species interactions

DeSimone J³, **Thomas-Bulle C**^{1,2}, Nemes C³, Tsuru B³, Anderson M^{3,4}, Berg C², Cohen E³

¹University of Lausanne, ²University of Montana, ³University of Maryland, Center for Environmental Science, ⁴Texas A&M University

POSTER SESSION 2 - P02.024, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The lack of inclusivity and diversity in evolutionary biology and ecology has been shown to affect the questions that are asked and the research that is published. Journals also play a critical role in either reinforcing or mitigating structural imbalances, and their editorial practices can strongly influence openness and representation across the field. A large proportion of studies in evolution and ecology focuses on species interactions, including competition, predation, and mutualisms, which play a central role in shaping natural systems and evolutionary dynamics. Despite the prevalence and importance of a wide variety of species interactions, recent reviews have revealed that ecology journals and textbooks are dominated by studies of negative interactions like competition and predation, with much less attention paid towards mutualisms.

Given that scientists' identities and backgrounds influence the scientific questions they pursue, we test the hypothesis that one mechanism for ecology's focus on negative interactions is the historical overrepresentation of men among published ecologists. We estimated

the gender of over 30,000 authors, based on their names, of approximately 9,000 papers published in 13 leading ecology journals over the past 25 years and found a strong association between author gender and the type of interaction studied with no influence of the author's geographical affiliation and the studied taxa. Women are significantly more likely to study positive interactions like mutualisms, whereas men are more likely to study competition and predation. This gender pattern holds across author positions but is even more pronounced among last authors. While women are not inherently more cooperative than men, they are often socialized to be, and socialized gender norms may influence scientific interests.

We further analysed how these patterns have shifted over time by extending our study to the past 50 years and found that as the number of female authors increases, so does the richness of interaction types. Our study provides original evidence that increasing diversity within scientific fields broadens our understanding of the natural world and contributes to a more inclusive and trustworthy evolutionary biology community.

Psychological insights for building accessible R Shiny apps in ecological and evolutionary modeling

Ghenu A¹, Grinschgl S¹, Peischl S¹

¹University Of Bern

POSTER SESSION 2 - **P02.022**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Mathematical models are essential for managing environmental and health challenges, yet they can be notoriously inaccessible to students and researchers alike. A research gap exists where we know math is inaccessible, but we do not know exactly why. This project aims to enhance the accessibility to mathematical models in ecology and evolution by developing evidence-based strategies for designing and disseminating interactive web apps.

We are conducting a psychological study to identify app design features that best support bachelor student learning and motivation. Our hypothesis is that students who interact directly with an app will perform better at creating their own model than those watching a video demonstration of the same app. Moreover, we test whether a modular app design, which progressively reveals model parameters, will reduce cognitive load and enhance learning compared to a fully revealed version. We recruited bachelor students from universities with English-language instruction for a 20-minute online learning task and randomly assigned them to app treatments as well as one of three case studies in ecology, evolution, or infectious disease. Each case study uses mathematically similar models — dynamical systems with alternative stable states and bistability — enabling us to assess a

common set of learning outcomes; students will understand i) the consequences of multiple attractors for the final state of the system and how these are impacted by ii) different parameter combinations as well as iii) initial conditions. By comparing participants' responses to case study-specific scientific questions before and after the learning task, we identified interactive app features that can best support different students in becoming better mathematical modelers. Our findings will improve educational strategies and enhance communication of mathematical models among researchers.

Our long-term goal is to establish a public, community-sourced database of interactive apps in ecology and evolution, which showcases and promotes the evidence-based design principles identified by our study. This database will provide educators with a rich pool of open-source resources and improve accessibility to research findings, for both researchers and change-makers, by offering interactive tools for visualizing new models. Presenting our preliminary findings and future project plans at this venue will foster collaborations and trust within the community. We welcome feedback to ensure this database becomes a valuable, inclusive resource for all.

SPI-Birds: increasing open, reliable and transparent analyses based on avian long-term monitoring in the wild

Fargevieille A¹, Vriend S², Burant J², Drouet M¹, Garcia Raventós A³, Hillemann F², Charmantier A¹, Teplitsky C¹

¹Centre d'écologie fonctionnelle et évolutive (CEFE UMR5175), ²Netherlands Institute of Ecology (NIOO-KNAW), ³Evolutionary Ecology Group - University of Antwerp

POSTER SESSION 2 - **P02.023**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Collecting long-term data on wild bird populations is historical in the field of ecology and widespread across the globe, providing valuable insights into evolutionary and ecological concepts. Yet, it seems there are as many ways to collect, enter and store data as there are existing datasets. Furthermore, for many datasets, metadata description is partial or lacking, drastically reducing the ability to reuse the collected data or to incorporate them in large-scale analyses. In addition, lack of metadata information on datasets from terminated projects may lead to data loss. To transition towards Findable, Accessible, Interoperable, Reusable (FAIR) data in avian evolutionary ecology, the Studies of individually-marked breeding birds (SPI-Birds) Network and Database (hereafter "SPI-Birds") was established in 2019 to offer a focused, centralized and well-defined grassroots community (Culina et al. 2021). SPI-Birds makes research groups and their datasets visible by enriching data with FAIR metadata, providing systematic data archiving, converting all datasets into a standard format and thus facilitating data sharing and comparative, cross-dataset analyses.

An important objective of the SPI-Bird project is to increase the transparency of the research lifecycle of the bird research community, including data processing and data analysis. SPI-Birds' core activities have expanded to encompass a work package dedicated to improving Open, Reliable and Transparent analyses related to SPI-Birds

data. The aim is to connect the SPI-Birds database to a library of data processing and analytical tools, and to implement a code peer-review process for which we provide guidelines. Codes qualified to be included in the SPI-Birds code library are fitted to data in SPI-Birds' standard format, ensuring the codes themselves are standardized to increase functionality across different datasets (i.e. populations) standardized to the SPI-Birds standard format. As part of the project, we will invite users of SPI-Birds data to share their analyses codes (large-scaled quantitative genetics, selection analyses, etc.) in our code library. We will provide guidelines and a code review process to enhance openness, reliability and transparency of the shared codes.

This talk will be an illustration of the efforts developed by the SPI-Birds network to provide practical tools aimed at improving the application of FAIR principles to ecological data along with open, reliable and transparent analyses. Besides presenting some instances of large-scale analyses that used the SPI-Bird standard format, I will also present the different tools we are implementing to reach our aims of open, reliable and transparent analyses.

Currently, SPI-Birds hosts 165 studies covering 329 populations on 85 different species of birds. The ESEB conference is also a perfect opportunity to strengthen SPI-Birds network and increase the range of studies included.

Career breaks and care-giving: challenges and opportunities for flexible working in evolutionary ecology

English S¹, Santos E

¹University Of Bristol

MEETING ROOM 122+123, August 19, 2025, 2:00 PM - 4:00 PM

In biology, as in many other fields of research and society, we still face problems of gender equity (in progression and salary), and of women leaving the workforce. Some of this can be down to institutional barriers to progression, poor support during and after career breaks (e.g. maternity leave), and issues with culture. Here, we discuss our experiences of support before, during and after maternity leave and the impact this had

on our careers. We talk about flexible working patterns as a solution to support the return to work while balancing caring responsibilities, and our positive experiences of working part-time as academics. We recently set up a working group to discuss the challenges of being part-time and how institutions and individuals can better accommodate and support part-time workers.

Lessons learned from the COVID-19 pandemic on Open, reliable, and transparent practices

Débarre F¹

¹Cnrs / Sorbonne Université

MEETING ROOM 122+123, August 19, 2025, 2:00 PM - 4:00 PM

With the rapid emergence of variants with different transmission and antigenic properties, concepts and methods from evolutionary biology quickly became critical to studying the origin and spread of SARS-CoV-2, the virus causing COVID-19. The pandemic highlighted the need for open, reliable and transparent (ORT) practices for tracking SARS-CoV-2's evolution, adapting vaccines to these changes, and informing policy decisions. In this presentation, I propose to take a retrospective look at the challenges encountered, how they were

overcome, and whether lessons were learned – and remembered. I will focus in particular on matters related to genomic surveillance and data sharing, methodological advances for phylogenetic analyses, issues related to reproducibility, publication practices from the use of preprints to the availability of articles. I will discuss the importance of ORT for informing public health responses and ensuring trust from the public, and how ORT will be critical to better pandemic preparedness.

Three species, three labs, three experiments: testing the reproducibility of evolutionary-ecological studies on insect behaviour in a multi-laboratory setting

Mundinger C¹, Schulz N¹, Singh P², Janz S², Schurig M¹, Seidemann J³, **Kurtz J¹**, Müller C², Schielzeth H³, von Kortzfleisch V¹, Richter H¹

¹University of Münster, ²Bielefeld University, ³Friedrich Schiller University Jena

MEETING ROOM 122+123, August 19, 2025, 2:00 PM - 4:00 PM

The reproducibility of studies involving insect species is an underexplored area in the broader discussion about poor reproducibility in science. Our study addresses this gap by conducting a systematic multi-laboratory investigation into the reproducibility of evolutionary-ecological studies on insect behaviour. We implemented a 3 x 3 experimental design, incorporating three study sites, and three independent experiments on three insect species from different orders: the turnip sawfly (*Athalia rosae*, Hymenoptera), the meadow grasshopper (*Pseudochorthippus parallelus*, Orthoptera) and the red flour beetle (*Tribolium castaneum*, Coleoptera). Using random-effect meta-analysis, we compared the consistency and accuracy of treatment effects on insect behavioural traits across replicate experiments. We successfully reproduced the overall statistical treatment effect in 83% of the replicate experiments, but overall effect size replication was

achieved in only 66% of the replicates. Thus, though demonstrating sufficient reproducibility in some measures, this study also provides first experimental evidence for cases of poor reproducibility in insect experiments. Our findings further show that reasons causing poor reproducibility established in rodent research also hold for other study organisms and research questions. We believe that a rethinking of current best practices is required to face reproducibility issues in insect studies, but also across disciplines. Specifically, we advocate for adopting open research practices and the implementation of methodological strategies that reduce bias and problems arising from over-standardization. With respect to the latter, the introduction of systematic variation through multi-laboratory or heterogenized designs may contribute to improved reproducibility in studies involving any living organisms.

Towards an open and responsible publication model

Radwan J¹

¹Adam Mickiewicz University

MEETING ROOM 122+123, August 19, 2025, 2:00 PM - 4:00 PM

Publication in scientific journals relying on peer review to ensure reliability is a dominating model of scientific communication, but with an exponential increase in the number of articles published in the last decade, the model becomes dysfunctional, putting the credibility of science in threat. I will review evidence for this crisis, including an increasing share of papers produced in papermills that find their way even to highly indexed journals. The crisis reflects increasing pressure for journals to publish more articles, and difficulties editorial boards encounter in contracting good-quality reviews, a consequence of ever increasing number of article submissions. I will argue that the crisis is significantly associated with currently predominating open access publication model based on so-called article processing charges (APCs), which turn scientific publishing into billion-euros industry. I will illustrate the resulting conflict of quantity vs. quality with publicly known cases of resignations of editorial boards being under pressure to accept and an ever increasing number of articles. Another highly undesirable consequence of article

processing charges is a barrier they impose for scientists from the global south. This diagnosis suggests ways to solve the crisis. The solution should re-direct taxpayer money now spent on APSs to high-quality subscription-based publishers guaranteeing open access and high peer-review quality, for example, guaranteed by recognised societies like ESEB. In particular, publishers supported from public money should guarantee: (1) open access publication of a pre-negotiated number of articles per year, which will remove the incentive to publish more articles; (2) publicly known subscription rates to prevent unjustified revenues of publishers; (3) high quality peer reviews, which could be assessed by panels of experts. No restrictions should be imposed on publishers as to the affiliations of the authors in order to prevent geographic barriers to open publishing. The peer review crisis could be addressed by recognising reviewing process as an important scientific activity, whose quality should be assessed along with more traditional scientific achievements. This would need to involve open peer review, with likely additional positive effects on review quality.

S12 - Epigenetics and adaptation to global change: climate and biotic interactions

Developmental plasticities within and across generations in *Austrolebias* annual killifish

Van Dooren T, Olijerhoek J

POSTER SESSION 3 - **P03.044**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Predictions of global change responses need estimates of phenotypic plasticities. During development, embryos experience different interacting environmental effects, while their individual state is in part determined by their parents. Developmental plasticity to cues which parents or offspring experience can be active or passive. Either can be maladaptive, when that would decrease long-term fitness.

Annual killifish live in temporary ponds with egg banks of developing and diapausing embryos persisting through dry periods. Embryos of the Argentinian pearl killifish *Austrolebias bellottii* were subjected to three crossed environmental treatments, of which one was applied to their parents. Embryos were incubated in water that housed adult fish or not. They were incubated at four different temperatures. Parents experienced short- or long daylength regimes.

Effects on fitness components were estimated, namely stage-specific survival rates and rates of development. Multi-state models were used to predict distributions over developmental stages with age.

We found an overall acceleration of events with temperature, less pronounced for

mortalities. The data suggested that optimal temperatures for survival differ between stages. There were some effects of parental light regime and signals of adults in the water on embryo survival. Convergence to a diversified bet-hedging distribution of diapause stages occurred in each temperature. It is unclear whether this stability involved any active response. A deceleration of late development occurred in high temperatures when parents experienced the short day light regime. It is consistent with the idea that annual fish multigenerational reaction norms are adapted to a regular annual seasonal cycle. Overall, the data suggest that developmental plasticity is rather passive. Part of the variation in outcomes is due to mortality plasticity. Patterns which can be explained as adaptations combine adaptation to a regular seasonal cycle by a parental effect, and maybe diversified bet-hedging. However, this assumes adaptation to the past and it remains to be seen how climate change will change adaptiveness.

DNA methylation footprint of fisheries in genetically homogeneous marine metapopulations

Barcelo-Serra M¹, Van Oers K², Alós J¹

¹IMEDEA (CSIC-UIB), ²NIOO-KNAW

POSTER SESSION 3 - **P03.012**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Trait selective harvesting by fisheries can impose selective pressures that can induce measurable changes in fish life histories, ultimately affecting fisheries productivity and ecosystem functioning. While the genetic consequences of harvesting have been extensively studied, the extent to which variation on phenotypic traits reflects genomic evolution versus environmentally-induced plasticity remains unresolved. DNA methylation may mediate between these mechanisms, acting as a rapid, environmentally responsive regulatory process. In this study, we examined both, genomic variation and DNA methylation patterns in the marine fish *Xyrichtys novacula* across three geographical areas comprising two adjacent sites subject to contrasting fishing pressures; including a no-take Marine Protected Area (ntMPA) and an exploited fishery. A nested analysis design across the three spatial replicates, revealed strong gene flow and no evidence of genetic

structuring between sites. However, significant reductions in nucleotide diversity were observed in fisheries relative to ntMPAs, suggesting an increase in genetic diversity linked to protection. In contrast, DNA methylation differences revealed a more pronounced and consistent divergence across protection levels and geographical areas, suggesting an effect of fishing pressure on DNA methylation patterns. We identified numerous differentially methylated CpG sites, primarily located within coding regions, including both introns and exons. These sites were associated with genes involved in metabolic regulation and neural development, suggesting a potential role for DNA methylation in mediating phenotypic plasticity in response to fishing pressure. Our work represents one of the first lines of evidence that fisheries may exert evolutionary influence via DNA methylation modifications without altering the underlying the DNA sequence.

Epigenetic factors associated with diel vertical migration and diapause in the marine copepod *Calanus finmarchicus*.

Zejc K¹, Martin S¹, Last K², Wenzel M¹

¹University Of Aberdeen, ²Scottish Association for Marine Science

POSTER SESSION 3 - **P03.061**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

As ocean temperatures increase due to climate change, many temperate marine species are experiencing habitat range shifts to higher latitudes. One such species is *Calanus finmarchicus*, an abundant copepod in the North Atlantic Ocean, where it serves as a food source for higher trophic levels and plays a key role in biogeochemical carbon cycling by consuming phytoplankton and moving fixed carbon to the deep ocean. *C. finmarchicus* displays two migration behaviours crucial to its ecological role, i.e. diel vertical migration (DVM) and seasonal migration behaviour associated with developmental diapause. While DVM follows a circadian pattern, with copepods ascending to the surface to feed at night and descending to deeper water during the day to avoid predators, diapause occurs in late spring when copepods in their penultimate copepodite stage migrate to the deep sea where they remain inactive for 7-8 months. Photoperiod may play a significant role in regulating both DVM and the timing of diapause, implicating phenological shifts in seasonal cues as major potential disruptors of *Calanus* ecology with cascading effects on marine ecosystems. However, our understanding of the extent of phenotypic plasticity in their migration behaviours and the underpinning physiological and

molecular processes remains limited. Epigenetic mechanisms, such as DNA methylation, are important sources of molecular plasticity in response to environmental stimuli and affect gene expression and higher phenotypes. While the role of epigenetics in chronobiological processes has been explored in vertebrates and terrestrial invertebrates, it remains understudied in marine invertebrates. Here, I identify the role of DNA methylation in DVM and diapause in *Calanus finmarchicus* behaviour using samples of this species from temperate (Loch Etive, West Scotland) and sub-Arctic (Fram Strait, Greenland Sea, Svalbard) locations. Using Enzyme-Linked Immunosorbent Assay (ELISA) and rhythmic analysis, I tracked genome-wide methylation changes through the circadian and circannual cycles. I identified locus-specific methylation changes in circadian and diapause-associated genes by real-time quantitative PCR (qPCR). Preliminary data revealing rhythmic global DNA methylation changes suggest epigenetic involvement in endogenous control of migration behaviours in *Calanus*. This work offers new insights into the molecular basis of these crucial behaviours and lays the foundation for microcosm experiments that will enable mechanistic insight into these processes.

Epigenetic response of mountain hare (*Lepus timidus*) in different climate zones

Marinangeli L^{1,2,3}, Korkuc P³, Vullioud C³, Meneghini D³, Auls S³, Crestanello B¹, Pedersen S⁴, Melo-Ferreira J⁵, Nonnis-Marzano F², Fickel J^{3,6}, Hauffe H^{1,7}, Weyrich A³

¹Fondazione Edmund Mach, ²Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma (PR), Italy, ³Department of Evolutionary Genetics, Leibniz-Institute for Zoo and Wildlife Research (IZW), Alfred-Kowalke-Str. 17, Berlin, D-10315, Germany, ⁴Faculty of Applied Ecology, Agricultural Sciences and Biotechnology, Inland Norway University of Applied Sciences, Koppang, Norway, ⁵BIOPOLIS Program in Genomics, Biodiversity and Land Planning, CIBIO, Vairão 4485-661, Portugal, ⁶University of Potsdam, Karl-Liebknecht-Str. 24-25, Potsdam, D-14476, Germany, ⁷National Biodiversity Future Centre (NBFC), Piazza Marina 61, 90133 Palermo, Italy

POSTER SESSION 3 - **P03.002**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The mountain hare (*Lepus timidus*) is a boreal mammal with a wide distribution across northern Europe, ranging across dramatically different climate zones, from mild winters in Ireland and strong winter conditions like in the Alps and Norway. Here, we investigated DNA methylation patterns in liver samples from individuals legally hunted in these three areas to investigate whether epigenetic responses varied among individuals. Pairwise population comparisons showed that differentially methylated regions were located in genes involved in pathways determining thermoregulation, pigmentation and developmental processes linked to body size. In addition, epigenetic distances between populations mirrored previously

published genetic distances for the same populations, and several differentially methylated genes were those reported to have fixed alleles. In both pairwise comparisons including Ireland (which do not universally moult to a white pelage in winter) pigmentation genes were hypomethylated. Comparing Alpine (smaller body size) and Norwegian (larger) hares, the latter had mostly hypomethylated genes in the pathway developmental process assumed to underlie the observed differences in body mass index. This indicated that in addition to genetic changes, epigenetic modifications may also contribute to the molecular basis of Bergmann's rule. Overall, our results suggest that epigenetic mechanisms may increase adaptability to rapid environmental changes.

Epigenomic profiles underlying induced defenses in a freshwater gastropod

Perisa D¹, Meuthen D¹

¹Bielefeld University

POSTER SESSION 3 - **P03.033**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Phenotypic plasticity describes the ability of a genotype to differentially express phenotypes in response to environmental cues. A well-studied instance of plasticity are the phenotypic changes triggered by cues indicating predation risk, also known as inducible defenses. One pivotal model for studying these defenses is the freshwater gastropod *Physella acuta*, where damage-released cues from conspecifics (i.e., alarm cues) are known to induce changes to their behavior, morphology and life-history that are beneficial in a predation context. Despite extensive research on these phenotypic changes, the underlying gene expression profiles remain largely unexplored. In this study, using *P. acuta*, we employed a split-clutch design to investigate risk-induced changes in gene accessibility. One half of full siblings was raised from hatching onwards in

a high-risk environment, i.e., under continuous exposure to conspecific alarm cues. The other half was raised in a low-risk water control environment. We sampled snails' behavior and morphology at sexual maturity, shortly before obtaining foot tissue for ATAC-sequencing. Differentially expressed open chromatin sections between risk treatments will then be characterized using our functional annotation of a recent *P. acuta* genome assembly. We will not only showcase treatment-dependent up- and downregulation of *P. acuta* genes but also correlate them to individual phenotypic changes. This research aims to elucidate epigenomic changes underlying phenotypic plasticity, thereby contributing to an improved understanding of the molecular mechanisms driving adaptive responses within single generations.

Evolutionary Trade-offs Between Intergenerational and Transgenerational Fitness Effects

Harris I¹, Duxbury E¹, Immler S¹, Chapman T¹, Maklakov A¹

¹University Of East Anglia

POSTER SESSION 3 - P03.045, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Intergenerational and transgenerational fitness effects can shape evolutionary processes. Theoretically, however, intergenerational and transgenerational effects can trade-off with each other with profound consequences for population dynamics. Here we show that beneficial intergenerational effects that increase offspring fitness can result in detrimental transgenerational effects that decrease great-grand offspring fitness. We used theoretical and experimental techniques to investigate transgenerational fitness effects of larval starvation in *Caenorhabditis elegans*. We show that individuals who undergo larval starvation exhibit large decreases in multiple fitness estimates.

However, regardless of offspring environment, their immediate descendants gain fitness benefits whilst great-grandchildren suffer fitness costs. Through simulating boom-and-bust population dynamics, we find an adaptive evolutionary strategy where beneficial intergenerational effects trade-off with detrimental transgenerational effects to increase fitness of a genotype across many generations. Our findings suggest that such multigenerational trade-offs will play an important role in evolution and challenge the view that transgenerational effects are necessarily adaptive.

Evolved transcriptional responses and their regulation after long-term adaptation of *Bemisia tabaci* to a marginally-suitable host

Tadmor E¹, Juravel K², Grandebul N¹, SANTOS GARCIA D³, Marshall H⁴, Morin S¹

¹Department of Entomology, the Hebrew University of Jerusalem, Rehovot, Israel, ²Koret School of Veterinary Medicine, The Robert H. Smith Faculty of Agricultural, Food & Environment, The Hebrew University of Jerusalem, Rehovot, Israel, ³INRA, CIRAD, IRD, Montpellier SupAgro, University Montpellier, France, ⁴Department of Genetics and Genome Biology, University of Leicester, UK

POSTER SESSION 3 - **P03.089**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Although invasive generalist insect herbivores can migrate and rapidly adapt to a broad range of suitable host plants, they can face significant difficulties when accidentally migrating to novel and marginally-suitable hosts. What happens, at both the genome-wide regulatory and transcriptional levels, if these marginally-suitable hosts must be used for multiple generations before migration to a suitable host can take place, largely remains unknown. Moreover, if adaptation to the new marginally-suitable hosts and transcriptomic changes do occur, how are they regulated? Does it involve changes in epigenetic patterning and processing (such as alterations in DNA methylation) and/or sequence changes in cis- or trans-regulatory elements in the genome (such as enhancers and promoters)? Using as a model the invasive and generalist whitefly species, *Bemisia tabaci*, we established a multi-generational experimental system that allowed us to explore the evolved differences between two populations that were subjected to cotton (a suitable host) and habanero-pepper (a marginally-suitable host) on which the initial survival is 5%.

First, we conducted reciprocal host performance assays under both optimal (30°C) and mildly stressful (24°C) temperature conditions to assess the adaptive changes in the two populations. We found that the habanero-adapted population exhibited a substantial increase in survival on habanero pepper (exceeding 60%) but did not reach the survival rates observed on the original cotton host (80–90%). Furthermore, this population displayed a trade-off, exhibiting reduced performance on cotton relative to the non-adapted population, and an antagonistic interaction with temperature stress at 24°C. Transcriptomic profiling revealed that adaptation to habanero pepper was associated with two major molecular changes: (1) an upregulation of genes involved in cuticle

structural component synthesis and (2) a downregulation of genes encoding cysteine-type peptidases, particularly cathepsin B proteins, which are implicated in the activation of plant defense responses.

Next, we analyzed the evolution of 5-methylcytosine (5mC) DNA methylation and single nucleotide polymorphisms (SNPs) in promoter regions after 34 generations. Our findings revealed only slight divergence in 5mC methylation levels between populations reared on suitable versus marginally-suitable hosts. These methylation differences were not directly correlated with changes in gene expression levels. Instead, we observed a strong association between 5mC methylation patterns, gene function, and expression variability. Housekeeping genes exhibited hypermethylation and lower expression variability, whereas environmentally responsive genes were hypomethylated and displayed higher expression variability. Additionally, SNP analysis in promoter regions suggested selection for specific alleles that may contribute to adaptive processes. These findings indicate that both epigenetic modifications and genetic variation in regulatory elements play a role in the multi-generational adaptation of invasive generalist herbivores to marginally-suitable hosts.

In conclusion, our study provides novel insights into the interplay between epigenetic regulation and genetic selection during host adaptation in invasive insect herbivores. The observed shifts in gene expression, 5mC methylation, and promoter-region polymorphisms highlight the complex mechanisms underlying long-term adaptation to suboptimal host plants. These results contribute to a broader understanding of how invasive generalists persist and evolve in novel environments, with implications for pest management and ecological resilience.

Experimental evidence for short term directional selection of epigenetic trait variation

Pujol B¹, Latutrie M¹, Luviano-Aparicio N¹, Mouginot P, Piquet J¹, Marin S¹, Maury S²

¹CNRS - CRIOBE, ²Université d'Orléans - Laboratoire de Biologie des Ligneux et des Grandes Cultures

POSTER SESSION 3 - P03.022, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Evolution by natural selection can occur when organisms harbor genetically inherited phenotypic variation, and phenotypic variants have differential fitness. Stable transgenerational epigenetic variation also exists for fitness-related traits and theory predicts that selection can act on this variation alone without a contribution of genetic variation. In this talk, I will present how we artificially selected for divergent biomass, rosette size, flowering time and height at first silique in experimental

Arabidopsis thaliana populations harboring DNA methylation polymorphism in an identical genetic background. We found significant epi-allele frequency changes in response to selection. Our results show how selection rapidly changed population trait values and their epigenetic basis, over one generation of selection. Our results imply the role of the transgenerational epigenetic variation of populations as an additional source of short-term adaptive potential.

Exploring the link between epigenetics and deleterious mutations

POSTER SESSION 3 - P03.085, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Quantifying the functional effects of genetic mutations is a central challenge in evolutionary biology. Beyond amino acid changes, mutations affecting gene regulation can also have fitness consequences. Here, we argue that, due to their pivotal role in gene regulation, epigenetic mechanisms likely modulate the expression and persistence of deleterious mutations. While epigenetics has been linked to inbreeding depression in model organisms, this connection remains largely unexplored in wild populations. Drawing upon evidence from humans and model organisms, we will highlight four potential interactions between epigenetics and deleterious mutations. We hypothesise that

epigenetic mechanisms could (i) be disrupted by deleterious mutations in non-coding regions; (ii) buffer the expression of deleterious mutations; and (iii) contribute to the repair and purging of deleterious mutations. Harnessing next-generation sequencing and bioinformatics, empirical testing of these hypotheses is both feasible and necessary. Unravelling the interplay between epigenetics and deleterious mutations is essential for assessing the fitness effects of genetic variants, which has significant implications for ecological and evolutionary processes, as well as for biological conservation, especially in a rapidly changing world.

Genetic and epigenetic responses of a keystone forest tree species to global climate change revealed through the integration of population-scale pangenomics and multi-omics analyses

Feng J¹, Cui Y¹, Zhang X¹, Zhu Y¹, Wang J¹

¹Sichuan University

POSTER SESSION 3 - **P03.054**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Global climate change poses a significant threat to ecosystem stability. Forests, as a key component of terrestrial ecosystems, play a vital role in the global carbon cycle. Unlike animals, plants are sessile and unable to escape unfavorable abiotic stresses through migration. Instead, they have evolved intricate mechanisms to adapt to environmental changes. Among these, rapid epigenetic modifications, along with changes in gene regulation and expression, represent critical and immediate responses to environmental stresses and resistance. However, our understanding of the relative contributions of genetic and epigenetic variations to both short-term abiotic stress responses and long-term evolutionary adaptations of populations to diverse climates remains limited. Here, we aim to integrate pangenomics, population genomics, and stress-induced multi-omics analyses to gain novel insights into how structural variations and transposon dynamics drive stress responses and adaptation to climate change, in conjunction with gene regulatory modulation and epigenetic modifications.

Materials and Methods: This study focuses on *Populus lasiocarpa*, a dominant and endemic alpine forest tree species with a ring-like geographic distribution surrounding the Sichuan Basin in central Asia. We integrated a 20 haplotype-scale pan-genome assembly, 200 population-scale whole-genome resequencing datasets, and various abiotic stress-induced (including heat, cold, drought, and waterlogging) RNA-seq, ATAC-seq, and Bisulfite-seq datasets to comprehensively explore how genetic variation interacts with gene regulation and epigenetic modifications. This approach aims to uncover the mechanisms underlying immediate stress responses and long-term evolutionary adaptations in natural populations of this keystone forest tree species.

Results: First, by combining HiFi long-read sequencing with Hi-C scaffolding technologies, we assembled 20 haplotype-scale genomes for ten representative individuals sampled throughout the natural distribution of the species. By integrating high-depth whole-genome resequencing datasets from 200 individuals across 22 natural populations, we constructed the pangenome of *P. lasiocarpa*

and identified structural variations (SVs) and transposon polymorphisms (TIPs) at the population scale across the entire genome.

Second, as these populations primarily group into two genetic clusters (western and eastern), we conducted greenhouse experiments to treat seedlings under various abiotic stress conditions. This allowed us to examine gene expression, chromatin accessibility, and methylation variations across both genetic clusters and stress treatments. We identified differentially expressed genes (DEGs), differential accessible chromatin regions (dACRs), and differentially methylated regions (DMRs) in response to abiotic stresses. These regions were further associated with pangenome characteristics, as well as dynamic SVs and transposable elements (TEs) across populations, to explore the interaction between genetic and epigenetic mechanisms in regulating stress responses and adaptation.

Lastly, we investigated the evolutionary forces acting on genomic variations and epigenetic modifications. We performed a distribution of fitness effects (DFE) analysis to assess the strength of purifying selection, as well as genotype-environment association (GEA) analyses to identify potential adaptive variants driving environmental adaptation. From these analyses, we selected candidate adaptive SVs and TIPs for experimental validation.

Conclusion: In summary, our study integrates pan-genomic and epigenetic approaches to comprehensively elucidate the molecular mechanisms underlying the responses to abiotic stress in *P. lasiocarpa*. This work provides valuable insights into both the immediate responses to environmental stresses and the long-term climate adaptation of these keystone species. Furthermore, we identified a set of adaptive variants, including both SVs and TIPs, that are strongly associated with gene regulation and stress responses, which offer a valuable genomic resource for future tree breeding programs aimed at enhancing adaptation to changing environmental conditions.

Identification of Fish Epigenetic Biomarkers of Temperature Response and parasite resistance shaped by Early Rearing Conditions

Huang W¹, Friis E¹, Thorland I², Fannemel B², Hitchings M¹, Mattanavile Shankregowd A¹, Moghadam H², Houston R², **Consuegra S**¹

¹Department of Biosciences, Swansea University, ²Benchmark Genetics

*POSTER SESSION 3 - **P03.001**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

Environmental variation can trigger epigenetic changes that regulate gene expression without altering the underlying genetic information. Understanding this environmentally induced, non-genetic inheritance may provide valuable insights into phenotypic plasticity and adaptive evolution. In the context of climate change, rising temperatures are expected to influence disease dynamics, potentially altering pathogen resistance patterns in aquatic species. In this study, we aim to identify epigenetic markers associated with early rearing conditions, focusing on

temperature response and parasite resistance, using Oxford Nanopore sequencing. We analyze methylation differences between Atlantic salmon families reared under varying temperature conditions and when exposed to two pathogens: ISAV (Infectious Salmon Anemia Virus) and CMS (Cardiomyopathy Syndrome). Our findings offer new insights into how epigenetic mechanisms shape environmental responses in non-model species.

Temperature dependent DNA methylation in the Swedish sand lizard (*Lacerta agilis*)

Huften J¹, Olsson M², Husby A¹, Lillie M¹

¹Uppsala University, ²Gothenburg University

POSTER SESSION 3 - **P03.059**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Sand lizards (*Lacerta agilis*) are found across Europe, even stretching as far north to extremely cold environments such as in Sweden. Being highly adapted to such extreme temperatures makes them highly susceptible to climate change. Hence, we have been investigating how temperature may impact epigenetic mechanisms during egg incubation. Using an experimentally isolated, outbred, island population in southern Sweden we conducted temperature incubation experiments. Followed by reduced representation bisulfite sequencing of hatchling tail tissue to assess the role of temperature-dependent DNA methylation in early life stages and its thermolability. After identifying differentially methylated sites will determine their

association to promoters, gene bodies, intergenic regions and repeats, and follow up with gene ontology analysis to infer any impacts on gene function. Previous work on this dataset found thermolability of sex and sex-specific telomere dynamics, and using this additional existing data we aim to determine any epigenetic contributions to these dynamics. This study will greatly improve our understanding of epigenetic regulation in reptiles in general but also give us key insights into the impacts of climate change on the Swedish sand lizard in the near future. Our results, will help to inform the conservation of the species in Sweden, which will have to adapt to new seasonal temperatures as a result of climate change.

The epigenetic dimension of effects of climate change on alpine plants

¹Department of Botany and Biodiversity Research, University Of Vienna, ²Estación Biológica de Doñana, Consejo Superior de Investigaciones Científicas, ³LMU Biocenter, Faculty of Biology, Ludwig-Maximilians-University Munich

POSTER SESSION 3 - P03.015, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Climate change and extreme episodes of environmental stresses, notably heatwaves and droughts, have significant impacts on ecosystems and biodiversity. These stressors drive shifts in species distributions and demand rapid adaptation to ensure survival. The adaptive capacity of populations depends on heritable phenotypic variation that can be filtered by natural selection leading to locally adapted populations. However, it is questionable whether such adaptations can occur fast enough to keep pace with rapidly changing environments. Alongside long-term adaptive responses, shorter-term mechanisms underlying phenotypic plasticity can also contribute to successful persistence under environmental challenges. Among these mechanisms, the potential role of epigenetic variation—such as DNA methylation and its influence on gene expression—in acclimation and adaptation to climate change has been largely overlooked. Using transplantation experiments along altitudinal gradients, we investigate in natural habitats the molecular responses to climate warming of four representative unrelated high-alpine plant species, including *Luzula alpino-pilosa*, *Phyteuma hemisphaericum*, *Sibbaldia procumbens* and *Veronica alpina*.

To simulate the effects of climate warming in natural settings, we implemented a long-term in situ transplantation experiment, contrasting gene expression and DNA methylation across relocated plants from their native high-elevation habitats to lower elevation sites and high elevation control sites. This approach resulted in a consistent and ecologically relevant temperature increase of approximately 2.5°C during the growing seasons of the past four years, when compared to control plots relocated within the original elevation range. Importantly, this experimental design allowed us to study plant

responses under natural conditions while measuring survival and growth of the transplanted individuals.

Analyzing high-coverage short-read sequencing of enzymatically converted DNA libraries against newly assembled reference genomes, we detected significant variation in global DNA methylation levels induced by the temperature difference. In particular, under long-term temperature stress replicates exhibited increased variation in DNA methylation, compared to controls. Thousands of differentially methylated regions across the three types of sequence contexts of methylation in response to the warming treatment have also been recorded, most affecting regions outside of CDS. These changes suggest a potential epigenetic mechanism underlying plant acclimation to climate stress mainly driven from stochastic effects. Accompanying mRNA sequencing revealed a complex relationship between differential DNA methylation and changes in gene expression, underscoring the intricate regulation of plant stress responses at the molecular level. Functional enrichment analyses of both differentially expressed genes and differentially methylated regions point toward relevant stress-responsive functions and suggest a partial acclimation to the new, warmer conditions.

The insights gained are currently integrated with detailed ecological information from complementary projects to enhance our understanding of the extent and limits of biological responses to climate change in natural settings. Our findings grant a fuller appreciation of the spectrum of molecular and ecological implications of climate change and are expected to result in improved conservation strategies for alpine plants facing climate change.

Unveiling the genetic basis of floral seasonal phenotypic plasticity in the Moricandia genus

Sharma S^{1,2}, M. Gómez J^{2,3}, Armas C³, González-Megías A^{2,4}, Narbona E⁵, Navarro L⁶, L. Batanero G¹, Perfectti F^{1,2}

POSTER SESSION 3 - P03.078, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Phenotypic plasticity enables organisms to modify their phenotype in direct response to environmental changes. This crucial property may become essential in the era of climate change, as it may allow individuals to rapidly change their morphology, behavior, and physiology to endure increasingly stressful conditions. Central to this adaptability are shifts in gene expression, which environmental cues directly influence. Transcriptomics helps identify the genes and regulatory pathways activated in response to temporal or spatial environmental variations, providing insights into ecological acclimatization and short-term adaptation. *Moricandia arvensis*, a Mediterranean mustard, exemplifies the strength of phenotypic plasticity. This plant thrives in arid environments by adjusting its photosynthetic traits to withstand extreme summer conditions. Additionally, it demonstrates a striking floral polyphenism, producing two disparate flower types depending on the season. In the *Moricandia* genus, different species exhibit varying levels of plasticity in several floral traits, ranging from no plasticity

to extreme plasticity, such as the floral polyphenism seen in *M. arvensis*.

Materials and methods: To comprehensively understand the genetic basis of floral seasonal phenotypic plasticity in the *Moricandia* genus, we undertook a comparative transcriptomics analysis across various species of *Moricandia* under experimental spring and summer conditions.

Results: Our findings indicate that the intraindividual phenotypic shift between these two seasons is associated with crucial transcriptional changes in flowers. This analysis highlights shared gene expression patterns and species-specific responses, ultimately shedding light on the genes that contribute to seasonal phenotypic plasticity. Each species demonstrates unique transcriptomic responses while also exhibiting some common molecular signatures.

Conclusion: This research contributes to our understanding of phenotypic plasticity within the *Moricandia* genus and serves as a valuable model for investigating the evolution of phenotypic plasticity.

A Hardy–Weinberg Equilibrium–Based Neutral Model for Plant DNA Cytosine Methylation Variation

Ramesh A¹, Khvastow K, Müller J, Tellier A

¹Technical University of Munich

MEETING ROOM 120+121, August 22, 2025, 2:00 PM - 3:00 PM

Although some plant epigenetic marks are environmentally responsive, molecular studies have shown that other CG methylation variants can be stably transmitted across generations. Understanding how stably inherited CG methylation variation is maintained within populations is vital not only for elucidating the evolutionary basis of stable epigenetic variants but also for forecasting how environmentally responsive marks might influence population-level methylation patterns. However, our insight into the evolutionary significance of plant methylation variation has been limited by the absence of a neutral null model. To address this gap, we developed a Hardy–Weinberg equilibrium (HWE)–based null model and used it to test how observed methylation-state frequencies deviate from neutral expectations.

In classical HWE, allele and genotype frequencies remain constant in a large, randomly mating population free of selection, mutation, migration, and drift. We adapted this framework to methylation epialleles by modeling the distribution of methylated (M) and unmethylated (U) genotypes under neutrality. Any excess or deficit of M/M, M/U, or U/U epigenotypes thus flags non-random processes—selection, environment-induced change, or drift.

We further incorporated two methylation-specific features observed in *Arabidopsis thaliana*: (1) a slightly higher rate of loss of methylation ($M \rightarrow U$) than gain ($U \rightarrow M$), and (2) hybrid-specific remodelling (transchromosomal methylation/demethylation, TCM/TCdM), which can produce additive or non-additive patterns. We then ran finite-population simulations, including scenarios of selfing (reflecting *A. thaliana*'s mating system) and

demographic expansion, to generate methylation site frequency spectra (mSFS) under (a) neutrality, (b) neutrality plus selfing, and (c) neutrality plus population expansion. Neutral models incorporate biased epimutation rates and methylation remodelling.

Our results show that TCM/TCdM exerts the strongest influence on methylation-state variation; biased epimutation alone drives fixation toward U/U, but remodeling maintains polymorphism in a population. Selfing reduces heterozygous (M/U) states, with overall diversity shaped by the balance between selfing and TCM/TCdM. Population expansion reduces variance and reduces the time to fixation. It results in the characteristic U-shaped mSFS, which indicates an excess of rare methylation states, that has been observed in *A. thaliana* populations.

This is the first neutral, population-genetics–based model specifically for plant methylation. By integrating known molecular mechanisms in *A. thaliana* with classical evolutionary theory, we demonstrate that epigenetic remodeling is the principal force maintaining variation. In contrast, biased epimutation, selfing, and demography contribute to an excess of rare methylated and unmethylated states, with unmethylated states being more common due to the directional bias in epimutation rates. Our model lays the groundwork for future tests of non-neutral influences such as selection and migration on plant methylation variation. It is also useful to examine how the combined influence of environmentally inducible methylation states and transgenerationally stable methylation variants shapes epigenetic variation within populations.

DNA methylation: a way for fast adaptation in clonal species? An example with the plant species *Fragaria vesca* and adaptation to altitude.

Le Veve A^{1,2}, Sammarco I³, Latzel V³, Lafon Placette C²

¹IHPE lab, UMR5244, Univ Montpellier, CNRS, IFREMER, Univ Perpignan Via Domitia, ²Department of Botany, Faculty of Science, Charles University, ³Institute of Botany, Czech Academy of Sciences

MEETING ROOM 120+121, August 22, 2025, 10:30 AM - 12:30 PM

Given their sessile nature, plants need to constantly respond to changing environments, i.e. show phenotypic plasticity, essential in the context of climate change. DNA methylation and other epigenetic modifications may enable rapid adaptation to environmental changes by generating locally adapted phenotypes. However, the epigenome is not usually considered a mechanism for long-term adaptation that can respond to selection, due to the potentially limited inheritance of epigenetic marks, especially during sexual reproduction, where epigenetic resetting occurs during meiosis. However, clonal propagation in plant bypasses this resetting process. In clonal species, epigenetic variation (or epi-allele) might serve as a substrate for selection, and could be particularly important for long-term adaptation, especially if clonal propagation is associated with reduced genetic diversity. This assumption remains, however, to be tested in natural populations.

Among all epigenetic marks, DNA methylation has received the most attention in evolutionary studies. In plants, DNA methylation occurs in three sequence contexts: CG, CHG and CHH. DNA methylation variation arises at a considerably higher rate than genetic mutations in response to genetic, environmental and stochastic factors. In all sequence contexts, epi-allele plays a pivotal role in repressing the mobilisation of transposable elements, but only CG and CHH methylation appear to be connected to gene expression. Thus, epi-alleles, as genetic mutations, meet all the criteria required for natural selection to act in clonal species: they can vary within and between natural populations, be inherited across generations, and influence individual fitness.

Using population genomics approaches, we investigated whether epi-alleles are subject to

natural selection in the clonal plant *Fragaria vesca*. This species has a wide natural distribution and can inhabit a range of altitudinal environments. In this study, we focused on from three low- and four high-altitude Italian populations which a substantial amount of publicly genomic, epigenomic, and transcriptomic data existing for clones cultivated under common garden conditions. The environmental effects on epi-alleles were minimised by the cultivation in common garden, allowing us to focus on inherited epi-alleles that may have been selected in response to altitude gradient in ancestral populations.

First, we demonstrated that CG and CHG patterns clustered individuals by ancestral populations and altitude of origin, and these pattern were only partially explained by genetic variations. Moreover, the linkage disequilibrium between epi-alleles appeared to be independent to genetic variations. These two observations suggested that epi-alleles, including them under natural selection, are partially independent of the genetic variations. Employing the classical fixation index, we identified 136 heritable candidate regions under altitudinal selection. These loci overlapped with genes involved in the O-methyltransferase activity. However, only one of them overlapped with epi-alleles associated with altitude by epigenome-wide association (EWA) approach and none of them was associated with the phenotypic traits measured. Finally, we distinguished epi-alleles under selection that were regulated by genomic variation, revealing that most of the epi-alleles under selection in the two altitude groups were non-genetically determined.

These findings suggest that epi-allele could be an essential way of adaption in clonal species, potentially compensating for their low genetic variation.

Epigenetic differences from floater to territory holding male Namibian cheetahs (*Acinonyx jubatus*)

Weyrich A¹, Vullioud C¹, Melzheimer J¹, Wachter B¹, Fickel J¹

¹Leibniz Institute For Zoo And Wildlife Research

MEETING ROOM 120+121, August 22, 2025, 10:30 AM - 12:30 PM

Within a lifespan, one genotype can bring about several phenotypes. Epigenetic mechanisms are strong candidates of molecular regulation for more rapid phenotypic changes. While changes within the DNA sequence are rare and slowly accumulate over generations, DNA methylation can change flexibly, regulate gene expression, and have the potential to increase adaptability of species facing environmental alterations. In free-ranging cheetahs, adult males can change their spatial tactics from roaming over large distances (“floater male”) to occupying a territory (“territorial male”). In consequence of such an event, males decrease their movement activity, undergo physical changes by increasing body mass, and show reduced anxious behaviour towards humans. With our study, we aimed to identify whether the change in spatial tactic changes DNA methylation patterns, whether genes and physiological pathways are affected associated with the observed phenotypic changes, and whether we can select epigenetic biomarkers that predict spatial

tactic of male cheetahs. Blood of ten free-ranging Namibian male cheetahs was taken twice, first when they were floaters and second after becoming territory holders. DNA from peripheral blood mononuclear cells (PBMCs) was enriched for methylated DNA by capture via methyl-binding-domain protein 2 (MBD2) and subsequent high-throughput sequencing (MBD-Seq). Using the methylation patterns from each individual's floater period as baseline, we detected 442 hypermethylated and 20 hypomethylated genes after cheetahs had become territorial. Differentially methylated genes were enriched in 23 pathways including development of anatomic structure, system, organ, nervous system, regulation of cell communication and signaling. The observed pathways associated with the observed behavioral, physiological and morphological changes, and indicate that DNA methylation might be important in the molecular regulation of shifting between spatial tactics in male cheetahs.

Epigenetic potential and range expansion in the house sparrow

Martin L¹, McCain K¹, Kohl K², Schrey A³

¹University Of South Florida, ²University of Pittsburgh, ³Georgia Southern University

MEETING ROOM 120+121, August 22, 2025, 2:00 PM - 3:00 PM

House sparrows (*Passer domesticus*) are among the most common and broadly distributed vertebrates in the world. Although some of that success is due to the anthropophilic nature of the species, house sparrows also appear to have been successful colonizers because of their exceptional disposition to be plastic. In less than 200 years, sparrows have come to occupy all continents but Antarctica, and in the areas where they now reside, populations exhibit phenotypic patterns that suggest they have adapted to prevailing conditions much faster than would be expected from selection on standing genetic variation. In this presentation, we will summarize what we have revealed about the role of epigenetic potential in range expansions for this species, in particular how the CpG content of gene regulatory regions has enabled individuals to invade and thrive in new areas. We hypothesize that individuals that have high CpG density in gene promoters are better able to regulate expression of key genes. We think that this regulatory nimbleness protects them from novel and

threatening conditions common to new areas. In particular, we have been investigating how epigenetic regulation in the form of DNA methylation has helped sparrows cope with the diets they consume in new areas. A growing dataset from a variety of studies indicates that birds with the highest epigenetic potential are well-protected against gut pathogen infections (e.g., *Salmonella enterica*). Additional data indicate that these phenotypes manifest via DNA methylation of CpG sites in the promoters of the Toll-like receptor (TLRs) genes, sensors integral to surveillance for diverse pathogens. Indeed, TLRs are the first points of contact between pathogens and hosts, and moreover they determine the form and magnitude of host immune responses to microbes. Epigenetic potential in these genes in particular is probably adaptive and plastic because it enables individuals to mobilize the most promising immune response to an unknown threat in a manner that effectively balances the risks of mortality and morbidity with the energetic and nutritive costs of defense.

Epimutations in *Neurospora crassa*

Villalba de la Peña M¹, Kronholm I¹

¹University Of Jyväskylä

MEETING ROOM 120+121, August 22, 2025, 10:30 AM - 12:30 PM

While traditionally DNA sequence was considered to be the sole carrier of hereditary information, studies in recent years have revealed that epigenetic changes can contribute to heredity as well. While different definitions of epigenetics exist, we define epigenetic changes as changes in chromatin modifications, such as DNA methylation or histone modifications, that can be inherited.

If epigenetic changes can be transmitted across generations and it can contribute to phenotypic variation, as they potentially can as they can affect transcription, they can also be under selection. Theoretical studies have revealed that the properties of epigenetic variation will determine how epigenetic changes influence adaptation. To understand whether epigenetic changes are important for evolution, we must understand their properties.

We investigated the properties of epimutations in the filamentous fungus *Neurospora crassa*. To determine the rates spontaneous epimutations, that is spontaneous changes in DNA methylation and histone modifications, and to

understand where in the genome epimutation happen, we performed a mutation accumulation experiment, and sequenced MA lines across the pedigree. We observed that in *N. crassa* spontaneous DNA methylation changes do happen, but these are reliably transmitted across mitoses only in centromeric and pericentromeric regions. Rates of spontaneous DNA methylation changes are orders of magnitude faster than genetic mutation rates. With gain of methylation happening around $7-8 \times 10^{-6}$ per cytosine, and loss of methylation happening around $4-5 \times 10^{-4}$ per cytosine. Thus losses are around 50 times more common than gains. Ephemeral changes in DNA methylation do happen in euchromatic regions, but these are either not transmitted or their reversion rate is too fast to observe their accumulation in the MA pedigree.

Our results contrast to what has been observed in plants, and suggest that there are different pathways in *N. crassa* by which epimutations originate. We are currently testing this hypothesis using different mutants.

Maternal RNA variability as an adaptive feature of environmental responsiveness and heritable diversification

Adrian-Kalchhauser I¹, Stajic D¹, Berezenko A¹, Oberhänsli S¹

¹University Of Bern

MEETING ROOM 120+121, August 22, 2025, 10:30 AM - 12:30 PM

Heritable maternal RNAs are widely recognized as essential and highly conserved developmental cues. Yet beyond this canonical role, they may also function as sensitive indicators of environmental change and transmit adaptively meaningful information to the next generation. In organisms with high fecundity such as zebrafish, changes to the maternal RNA load may represent an adaptive bet-hedging strategy in the face of fluctuating environments. In particular, we are interested in change in maternal RNA variability, and investigate its role as signal rather than noise.

We thus currently investigate how heat stress influences the composition and variability of maternally deposited RNAs, and whether such changes are heritable across generations. In a multigenerational zebrafish experiment, fish were exposed to elevated temperatures for two weeks and mated at three post-stress timepoints (T1–T3). Unfertilized oocytes (up to 25 per mother) were collected individually, and subjected to RNA sequencing. They represent a transcriptionally and translationally stable stage, enabling high-resolution analysis of expression variability with minimal intrinsic noise.

The approach allows us to resolve maternal RNA variation at multiple levels—among eggs, within clutches, between mothers, and across treatments. Preliminary analyses reveal an increase in maternal RNA variability following heat exposure as well as an average increase in transcripts associated with the heat shock response. Principal component analysis and interquartile range metrics highlight numerous RNAs exhibiting treatment-specific variance shifts. Notably, gene expression patterns also correlate with maternal identity, suggesting an interaction between genetic background and environmental inputs in shaping variability.

These findings support the view that maternal RNA expression noise is not merely stochastic, but a potentially selectable trait modulated by stress. By characterizing its molecular drivers, functional identities, and transgenerational persistence, our work reframes gene expression variability as a critical axis of developmental and evolutionary plasticity. Together, these insights bridge developmental biology, epigenetics, and evolutionary ecology, and shed light on how organisms buffer and transmit information about environmental change through maternal contributions.

The role of epigenetics in local adaptation in sessile oak trees: a population epigenetic association study

MEETING ROOM 120+121, August 22, 2025, 2:00 PM - 3:00 PM

Rapid climate change is forcing species to either adapt very quickly, shift their geographic distributions, or face local extinction. This challenge is especially acute for long-lived, sessile organisms such as trees, which cannot migrate easily and whose extended generation times limit the pace of evolutionary response through genetic variation alone. Epigenetic mechanisms, including DNA methylation, have been proposed as a means by which organisms may respond more quickly to environmental shifts. In this study, we examine the role of DNA methylation in local adaptation across populations of sessile oak (*Quercus petraea*).

We analysed DNA methylation patterns in 189 individuals from 22 populations spanning a latitudinal gradient from Southern France to Northern Germany. All individuals were grown in a common garden experiment in Sillegny, France, which controlled for environmental variability and allowed us to isolate heritable components of epigenetic variation. Methylation data were generated using a targeted sequence capture approach focusing on regions known to be epigenetically variable, and targeting specific candidate genes (Lesur et al., 2024). Methylation data was then imputed in all three contexts for using NIPALS as tested in Duplan et al. 2025.

Exploratory data analysis revealed low variability and differentiation in the data. The global F_{st} for the SNP data was 0.001, and the global P_{st} of the methylation data was 0.008 in all three contexts. A PLS-DA across contexts by population also reflected the low variability as the first two axes only explained <6% of the variation. Overall, we observed low levels of

DNA methylation variation across the genome, with fewer than 5% of SMPs exceeding 0.05 inter-individual variation in any context (CG, CHG, CHH). For downstream analyses, we retained only the most variable 5% of SMPs per context.

Multi-omic association analyses were conducted using a multi-locus mixed model (MLMM) framework that incorporated phenotypic, climatic, single nucleotide polymorphism (SNP), and methylation (SMP) data. Despite the low overall variation, retained SMPs exhibited significant associations with four different phenotypic traits and 26 different climatic variables. Additionally, 40%, 49%, and 20% of tested SMPs in CG, CHG, and CHH contexts, respectively, were significantly associated with SNPs under the MLMM. There is however a significant amount of spatial autocorrelation in the associated SMPs which may explain the high levels of association, this is expected as nearby methylation marks are known to experience co-methylation.

Our findings indicate that while global DNA methylation variation is limited in our *Q. petraea* populations, specific methylation markers are associated with phenotypic traits and environmental gradients, pointing to a potential—but constrained—role for epigenetic variation in local adaptation in this species. Recognising this limited yet meaningful contribution is critical for understanding the mechanisms by which long-lived species may respond to rapid climate change, especially during the early stages of adaptation when genetic responses may be too slow.

Transgenerational transmission of epigenetic responses as a second driver of adaptive evolution

Edelaar P¹

¹University Pablo De Olavide

MEETING ROOM 120+121, August 22, 2025, 2:00 PM - 3:00 PM

Epigenetic molecular marking can be a mechanism for adaptation within generations, but also across generations. Transgenerational transmission of epigenetic responses is increasingly documented. I will first review how theoretical modelling has shown that when environmental change is too rapid for efficient genetic evolutionary tracking, this transgenerational transmission of epigenetic responses is expected to evolve. I will then argue that in the context of its ability to facilitate transgenerational change, epigenetic response is actually a subset of a wider category of organismal responses to ecological pressures. Subsequently, based on logical derivation and the Price equation, I will argue that organismal responsiveness, or plasticity in the broad sense, can be beneficially seen as a form of selection: as the non-random realization out of a set of options. When seen as a form of selection, broad-sense plasticity can then be seen as an alternative to natural selection for the adaptation of populations. With a reversed causality, here organisms are not selective targets, but selective agents. Following the logic of the breeder's equation (where evolutionary response $\approx$ selection pressure * degree of heredity), this alternative form of selection can thereby cause an evolutionary change in heritable traits when it is combined with non-genetic forms of heredity (as is sometimes the case for epigenetic responses but also for other organismal

responses). This combination of organismal plasticity (or response) and non-genetic inheritance hence provides a second driver of adaptive evolution. It could be summarised as “the selective production of heritable traits”. This can be contrasted with the classical driver of adaptive evolution, involving natural selection, or “the selective reproduction of heritable traits”. However, this additional second driver is only a driver of adaptive evolution if the organismal responses are adaptive. I will argue that this is not a given, but it is expected, since natural selection should act against maladaptive organismal responses. In this talk I therefore draw a parallel between the topic of the symposium, and the same issues for other forms of “selection” engaged in by organisms, such as trial-and-error learning, selective behavioural copying (cf. cultural evolution), partner choice (cf. social evolution), or habitat choice (cf. evolution of the extended phenotype). Epigenetic transmission is therefore a prime example of a wider discussion about the processes driving adaptive evolution. In the context of global change and evolutionary prediction, recognising the full spectrum of pathways towards organismal and evolutionary adaptation is perhaps more important than ever. (This talk is a partial summary of an Open Access book on adaptive evolution soon to appear at Oxford University Press.)

S13 - Evolution after whole genome duplication: transformative advances and new directions

A tektin gene family analysis of chromosome-level annelid genomes identifies an ancestral cluster of three tektin35B genes for one of the two major clades of Polynoidae/scaleworms

Mutiara S¹, Corpuz J², Schneider S¹

¹Academia Sinica, ²Adamson University

POSTER SESSION 1 - **P01.141**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Tektin proteins form structural components within microtubules particularly in cilia and flagella. They play primarily involved in the organization and stability of axonemal structures, and are essential for cell motility and are broadly present across metazoans. Given their functional importance, Tektins could be informative to gain insights into the emergence of novel cilia specializations within spiralian, a superclade of over 14 animal phyla including mollusks (e.g., snails) and annelids (e.g., earthworms). Previous work revealed that the ancestral condition of the tektin gene complement for spiralian genomes was five tektin genes: Three (tektin-2, -1, and -4) are of metazoan and bilaterian origin, while two, tektin-35A and -35B are spiralian specific ones that originated from a duplication of the bilaterian tektin-35 gene at the base of all spiralian. Marine annelids (polychaetes), among the most diverse spiralian groups represented by close to 100 families, most of which possess free-swimming larval stages that are propelled by motile cilia organized in ciliary bands or trochs.

Materials and methods: To gain further insight into the evolution of the tektin

complement within annelids, we analyzed over 20 chromosome level annelid genomes focusing on the larger subclades of Errantia and Sedentaria using reiterative BLASTX searches and subsequent phylogenetic analyses.

Results: Intriguingly, we found that tektin-1, -2 and -4 remained single copy genes in both subclades, while the two spiralian-specific tektins-35A and -35B were frequently duplicated. Of particular interest is the discovery of an ancestral cluster of three tektin-35B genes, and two duplicated tektin-35A genes in one of the major subclades of the scaleworms/Polynoidae, with similar duplications in the derived vent associated scaleworm *Branchipolynoe longqiensis*. In contrast, the single representative for the most basal polynoid clade *Lepidonotus clava* exhibits a more ancestral tektin gene complement of six with a potentially independent 35B duplication. **Conclusions:** This study identifies distinct molecular synapomorphies in regard to the tektin complement, shows the potential of this approach to identify unique cilia specializations within subclades of annelids, and to link these to phenotypes of ciliated larvae in the future.

Asymmetric genome merging leads to gene expression novelty through nucleo-cytoplasmic disruptions and transcriptomic shock in *Chlamydomonas* triploids.

POSTER SESSION 1 - P01.154, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

- Genome merging is a common phenomenon causing a wide range of consequences on phenotype, adaptation, and gene expression, yet its broader implications are not well understood. Two consequences of genome merging on gene expression remain particularly poorly understood: dosage effects and evolution of expression.

- We employed *Chlamydomonas reinhardtii* as a model to investigate the effects of asymmetric genome merging by crossing a diploid with a haploid strain to create a novel triploid line. Five independent clonal lineages derived from this triploid line were evolved for 425 asexual generations in a laboratory natural selection experiment.

- Utilizing fitness assays, flow cytometry, and RNA-Seq, we assessed the immediate consequences of genome merging and

subsequent evolution. Our findings reveal substantial alterations in genome size, gene expression, protein homeostasis, and cytonuclear stoichiometry. Gene expression exhibited expression-level dominance and transgressivity (i.e. expression level higher or lower than either parent). Ongoing expression-level dominance and a pattern of 'functional dominance' from the haploid parent was observed.

- Despite major genomic and nucleo-cytoplasmic disruptions, enhanced fitness was detected in the triploid strain. By comparing gene expression across generations, our results indicate that proteostasis restoration is a critical component of rapid adaptation following genome merging in *Chlamydomonas reinhardtii* and possibly other systems.

Challenging reproductive barriers between and within species: the role of ploidy in the genesis of new species

Frazão D¹, Castro M¹, Loureiro J¹, Castro S¹

¹FLOWer Lab, Centre for Functional Ecology – Science for People & the Planet, Associate Laboratory TERRA, Department of Life Sciences, University of Coimbra

POSTER SESSION 1 - P01.146, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole genome duplication (polyploidy) is a widespread phenomenon in nature and a key driver of plant evolution and diversification. However, newly formed polyploids (neopolyploids) often struggle to establish themselves due to frequency-dependent selection, where the more common parental cytotype inhibits their spread, a concept known as the minority cytotype exclusion hypothesis. Polyploidy typically leads to immediate reproductive isolation, but the role of triploids, which arise in diploid-tetraploid complexes, remains ambiguous. Theoretical models propose two contrasting roles for triploids: the "triploid block," which inhibits the establishment of new polyploids due to low fertility, and the "triploid bridge," which facilitates the formation of viable polyploid populations by producing viable gametes. Despite their theoretical importance, the frequency and conditions under which triploids act as blocks or bridges remain poorly understood. This study aims to evaluate the strength of reproductive barriers within and between different ploidy levels and species, using hand-pollination experiments in a common garden setting.

Different cytotypes of *Jasione maritima* and *Jasione montana*, two Mediterranean species from the Campanulaceae family with naturally occurring diploid and tetraploid individuals, were used as a model system. The pollination treatment consists of inter-cytotype crosses within and between species and intra-cytotype crosses within and between species with each cytotype acting as both pollen donor and recipient. Crosses were performed using three populations of each species and cytotype. To assess the reproductive success and isolation among cytotypes we examined fruit and seed production, seed germination rates and offspring ploidy. We hypothesize that whole genome duplication generates reproductive isolation comparable to that observed between species i.e., ploidy generates new entities reproductively isolated from parentals, the first step towards speciation. Our findings provide insights into the early stages of reproductive isolation in polyploid complexes, advancing our understanding of how polyploidy drives plant diversification and speciation.

Chromosomes, the more the merrier?

How does tetraploid *C. elegans* resist severe cold stress at the gravid adult stage?

Verdier C¹, Bazzani E¹, Souviraà-Labastie M^{1,2}, Atimise M¹, Mclysaght A¹, Chauve L¹

¹Trinity College Dublin, ²IUT Clermont Auvergne

POSTER SESSION 1 - **P01.150**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole genome duplication (WGD), or polyploidy, involves the duplication of an organism's entire genome and plays a major role in evolution. In early vertebrates, two rounds of WGD have coincided with mass extinction events, suggesting potential advantages in stressful environments. In plants, WGD is a well-established mechanism of speciation and stress resistance. In contrast, its role in animals remains unclear due to the rarity of WGD events.

Our research investigates the consequences of polyploidy and its potential short-term adaptive advantages under stress — a topic rarely explored in animals. We use *Caenorhabditis elegans*, where tetraploidy can be induced experimentally. Although tetraploid *C. elegans* display reduced fitness, fertility, and lifespan under normal conditions, they show improved survival and increased reproductive output following severe cold shock, suggesting a possible advantage under stress.

This project focuses on the role of lipid dynamics and reproductive status during and after cold shock. In diploid gravid adults, prior data in diploids suggest that vitellogenin-dependent lipid relocation from the intestine to embryos may contribute to post-severe-cold-stress mortality. Furthermore, we find that the survival of gonad-less diploid worms upon recovery from cold stress (CS) is similar to that of their tetraploid counterparts. We hypothesise that tetraploid worms survive upon recovery from CS, either because of metabolism/lipid localisation alterations, and/or germline alterations. We investigate how the lipid dynamics occurring in tetraploids compare to the ones in diploids, and whether cold-

induced mortality is influenced by specific reproductive factors such as germline activity and reproductive state.

To examine lipid distribution during recovery, we perform BODIPY lipid staining on cold-shocked wild-type diploid and tetraploid *C. elegans*. This allows us to visualize lipid localization patterns and assess whether tetraploids exhibit differences in intestinal lipid retention or redistribution compared to diploids, which could underlie their increased survival and reproductive output.

To further assess the contribution of reproductive factors to cold-induced death, e.g. whether the absence of embryos or fertilization alters sensitivity to cold, we use three *C. elegans* mutants: *fem-3(q20)*, which produces oocytes but is deficient in spermatogenesis, *fog-2(q71)* which comprises feminised XX individuals and WT XO males and *glp-1(e2141)*, which lacks germ cell proliferation.

Certain reproductive processes (allocation of lipids to the embryos, gonads integrity or germline proliferation) may contribute to cold-induced mortality, and their disruption could reduce the cost of reproduction under stress. If confirmed, this would support the notion that tetraploid resistance involves altered reproductive investment or changes in lipid trafficking. The outcomes of this study may reveal new mechanisms by which polyploidy buffers environmental stress and offer insights into the reproductive costs of extreme conditions.

Overall, this work seeks to connect cold stress survival with reproductive physiology and lipid metabolism, offering new perspectives on the adaptive potential of polyploidy in animals.

Consequences of induced whole genome duplication on the memory of environmental stress in tetraploid *C. elegans*

Bazzani E¹, Verdier C¹, Phelan A¹, McLysaght A¹, Chauve L¹

¹Trinity College Dublin

POSTER SESSION 1 - **P01.157**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Polyploidy is the result of a dramatic mutational event, the duplication of the entire genome. Whole genome duplication (WGD) is a natural phenomenon, particularly common and recognised as a major evolutionary force in plants. In animals, recent polyploid species are rarer, and the evolutionary advantage of WGD is more debated, as polyploidy also comes with substantial challenges.

Increasing evidence suggests that WGD-induced changes in cell and nuclear geometry are critical factors contributing both to challenges and to potentially beneficial novelties observed in neopolyploids. Decreased nuclear surface-to-volume ratio, for example, can influence chromatin organization, and consequently, the distribution of repressive histone marks. Moreover, nuclear geometry is also directly linked to the regulation of stress responsive genes.

This research aims to investigate the short-term consequences of WGD on the epigenetic landscape of tetraploid animals and the outcomes for the memory of stress responses. Using *Caenorhabditis elegans* as a model, we are able to experimentally induce WGD and obtain genetically identical tetraploid animals from almost any diploid strain. So far, studying autotetraploid *C. elegans* revealed that, although tetraploidy reduces fitness in regular conditions, tetraploids show increased resistance under temperature-related stress conditions, but is

the memory of such environmental stress affected after WGD?

Individuals exposed to a small dose of stress mount a stronger response when re-exposed to a higher dose of stress, a phenomenon called hormesis. While heat hormesis seems to be unaffected by WGD, we found the expression of a heat sensitive multicopy transgene to be increased in tetraploids. Measuring the fluorescence levels of this multicopy transgene allows to (indirectly) observe the behaviour of heterochromatin, specifically that of repeated elements. Moreover, temperature-induced changes in the expression of this array have been shown to be heritable across several generations. Therefore, observing increased expression levels of this multicopy array following WGD led to the hypothesis that its inheritance might also be affected. Our preliminary experimental data suggest that WGD might in fact alter the transgenerational memory of heat stress, through de-repression of repeated elements. Coupled with this, immunofluorescence on key histone modifications, along with qRT-PCR of endogenous repeated elements (e.g., transposons), will provide further information on whether the distribution of repressive histone marks is altered in tetraploid worms.

This work aims to link WGD-induced nuclear perturbations and altered stress responses in polyploid animals, potentially through epigenetic remodelling and changes in the distribution of histone modifications.

Dynamic Transposon Activation and Gene Regulatory Rewiring Drive Functional Divergence of Duplicated Genes During the Rediploidization Process in *Orychophragmus violaceus*

Jia C¹, Hou Y², Zhu Y², Liu Y², Wang J²

¹University Of British Columbia, ²Sichuan University

POSTER SESSION 1 - **P01.144**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The regulatory and functional diversification and innovation that follow whole-genome duplication (WGD) are essential processes driving long-term evolution, particularly during the extended rediploidization process. Additionally, the dynamic activity of transposable elements (TEs) often coincides with WGD and rediploidization, playing diverse roles in genome evolution. TEs act not only as sources of genomic instability but also as drivers of regulatory innovation. However, our understanding of the evolutionary dynamics of duplicated genes and the mechanisms through which TEs contribute to gene regulatory innovation during rediploidization remains limited. *Orychophragmus violaceus* underwent a lineage-specific WGD approximately 13.4 million years ago and now possesses one of the largest genomes in the Brassicaceae family, largely due to a high proportion of transposon-derived sequences. This makes *O. violaceus* an excellent model for exploring the interplay between TE activity, gene regulatory evolution, and functional divergence during rediploidization.

Method and Materials: In this study, we de novo assembled a chromosome-level reference genome for *O. violaceus* and generated complementary multi-omics datasets from multiple tissues, including RNA-seq, whole-genome bisulfite sequencing (WGBS), and ATAC-seq from leaves, stems, roots, flowers, and siliques. Additionally, we obtained high-depth whole-genome resequencing data from 12 wild individuals for population genomic analyses.

Using these datasets, we quantified expression, DNA methylation, and chromatin accessibility divergence between duplicated genes following WGD, comparing these patterns with those observed in outgroup species. Furthermore, we identified genes exhibiting tissue-specific sub- and neo-functionalization and deciphered the mechanisms underlying their potential functional divergence. This was achieved by integrating multiple experimental validations, including luciferase reporter (LUC) assays, electrophoretic

mobility-shift assays (EMSA), and β -glucuronidase (GUS) assays.

Results: First, we observed a general bias toward reduced expression levels in paralogous genes following whole-genome duplication (WGD), likely as a mechanism to maintain gene dosage balance after ploidy changes. The downregulated genes were primarily associated with a high abundance of nearby transposable elements (TEs) and increased DNA methylation within gene bodies across CG, CHG, and CHH contexts.

Second, the analysis of duplicated genes revealed widespread divergence in expression levels, DNA methylation patterns, and chromatin accessibility between paralogs. Relaxed selective constraints were associated with both the rapid expression and sequence divergence of these gene pairs. Notably, compared to its paralog, which retained a conserved ancestral expression pattern, one of the duplicated diacylglycerol acyltransferase (DGAT) genes exhibited significantly higher expression in seeds, likely linked to the newly identified 24-carbon dihydroxy fatty acids found specifically in *O. violaceus*.

Lastly, we found that active TEs are strongly correlated with the divergence or emergence of new cis-regulatory elements, which are further linked to tissue-specific sub- and neo-functionalization of duplicated genes. Notably, using LUC, EMSA, and GUS assays, we experimentally validated a TE-associated, newly emerged flower-specific accessible chromatin region upstream of a copy of the Cinnamoyl-CoA reductase 2 gene (Ov-CCR2). This region contained a novel binding motif that can be preferentially activated by Ov-WRKY70, providing clear evidence that TE-associated regulatory innovation drives the functional divergence of duplicated genes.

Conclusion: Our findings demonstrated and experimentally validated that dynamic transposon activation during the rediploidization process played a pivotal role in rewiring gene regulatory evolution and driving functional innovation following whole-genome duplication in *Orychophragmus violaceus*.

Evidence for lineage-specific rediploidisation following the 1R whole-genome duplication at the base of the vertebrate lineage

Niezabitowski L¹, **Long R**¹, Redmond A², McLysaght A¹

¹Smurfit Institute Of Genetics, Trinity College Dublin, ²School of Medicine, University College Dublin

POSTER SESSION 1 - **P01.159**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Whole genome duplications (WGDs) - dramatic events in which the entire genome of an organism is doubled - have occurred multiple times in the evolutionary history of plants and animals. Two rounds of WGD (termed 1R and 2R) occurred at the base of the vertebrate lineage, with 1R occurring before the divergence of jawless and jawed vertebrates (cyclostomes and gnathostomes), and 2R being gnathostome-specific. A hexaploidisation event also happened in cyclostomes. WGDs provide much raw material for evolution and may have facilitated lineage survival during mass extinctions.

Following WGD, alleles are inherited tetrasomically. Only after the genome has returned to diploid, through the process of rediploidisation, can gene duplicates (ohnologs) diverge in sequence and function. Rediploidisation has been shown in some lineages to be a delayed and asynchronous process, occurring over millions of years, with cases where species divergence has occurred before rediploidisation is complete (Redmond et al., 2023).

We investigate evidence for lineage-specific rediploidisation following 1R, which previous studies have not supported. Lineage-specific rediploidisation allows for independent divergence of ohnologs resulting from the same WGD, and evolution of lineage-specific novelties, which may have interesting implications for the evolution of gnathostome genomes, including humans.

Materials and methods: We improve upon previous analyses, using recently released hagfish genomes, and utilising a high-confidence ohnolog dataset. We generate proto-vertebrate, proto-gnathostome, and proto-cyclostome reconstructions, incorporating genomic data from additional species compared to previous analyses. We combine topology and this macro-synteny

information for tree classification, and test for biases between pre- and post-speciation tree sets including in compositional heterogeneity.

Results: We successfully use macro-synteny information combined with tree topologies to classify previously uninformative trees featuring extensive gene loss, substantially increasing the amount of tree data available for investigation. We find evidence for lineage-specific rediploidisation following 1R, recovering high-confidence sets of pre-speciation and lineage-specific rediploidised ohnologs. Clear clusters by ohnolog type (pre-speciation or lineage-specific) are seen when these genes are mapped onto hagfish chromosomes, and chromosomes of gnathostomes, including humans. This adds confidence to our classifications and provides further evidence for lineage-specific rediploidisation following 1R.

Conclusions: We find evidence for lineage-specific rediploidisation following 1R. Our findings indicate regions of the genome had not rediploidised prior to the gnathostome-cyclostome split. As this allows for independent divergence of such ohnologs, lineage-specific rediploidisation may have facilitated the evolution of lineage-specific novelties seen in cyclostome and gnathostome genomes. Enrichment analysis and investigation and comparison of functions of pre- and post-speciation rediploidised genes may shed further light on the potential impact of delayed rediploidisation on vertebrate evolution.

³Department of Plant Biology, Swedish University of Agricultural Sciences

POSTER SESSION 1 - P01.156, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole-genome duplication (WGD) – resulting in polyploidy – has repeatedly occurred over evolutionary time, affecting all living organisms and particularly plants. WGD has been associated with major biotic and abiotic crises. Environmental stressors such as extreme temperatures tend to induce WGD. In turn, polyploid organisms typically show higher and/or broader tolerance to these stresses, enabling them to efficiently colonize suitable niches, even extreme habitats. However, WGD poses a serious challenge in the early stage of polyploid evolution, as it disrupts fundamental cellular processes and especially meiotic pairing and segregation. In nascent autopolyploids (within-species WGD), the presence of multiple homologous chromosomes may result in multivalent formations leading to instable meiosis and resulting in severe chromosome rearrangements or damage. Interestingly, meiotic instability seems often resolved in established autopolyploid populations while meiosis remains highly instable in neo-autopolyploids. Unfortunately, this has been poorly investigated in natural neo-

autopolyploid populations due to the scarcity of suitable model species. *Mimulus guttatus* (the “monkey flower”) is an emerging model species that has been studied for over 50 years due to its wide diversity of floral traits but also for its wide array of ecological and life traits. *M. guttatus* is native from America, but it has been introduced in Europe in the 19th century. Recent studies have found several autopolyploid populations along with known diploid ones in both the native and the invasive range. This sets up the perfect ground to investigate the genomic and functional mechanisms underlying the early adaptation to WGD, as well as to validate the role of meiotic stability in the evolutionary success of polyploidy in nature. To do that, we compared diploid and autotetraploid populations of *M. guttatus* between the native and the invasive range of the species, based on resequenced short-reads data and whole-genome scans. We identified several candidate genes and further characterized the impact of their genomic mutations to their resulting protein structure and function.

How does the common barbel (*Barbus barbus*) see? The effect of the whole-genome duplication on vision

POSTER SESSION 1 - P01.143, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Teleost fishes outstand among all vertebrates in the number of visual pigments and photoreceptor types. This extraordinary development was also facilitated by the teleost-specific whole genome duplication that occurred approximately 350 Mya. Here we explore teleost species that recently underwent subsequent whole genome duplication – the common barbel (*Barbus barbus*). This event was accompanied by hybridization (i.e., it was allopolyploidization) and resulted in 14 opsin genes found in the genome, an unusually high number even among teleosts. Does the expansion of opsin gene repertoire result in better visual abilities? We show opsin expression profiles of adult specimens and larvae at different developmental stages. Within three opsin classes (UV-sensitive SWS1, blue-sensitive SWS2, and green-sensitive RH2), we found opsin pairs with a clear temporal division of function – larval

and adult genes. Furthermore, the switch in expression from larval to adult gene copy in these opsin classes was synchronized – such effect has never been reported for a polyploid species. We investigated if such a division of function can be adaptive. We predict which opsin proteins differ in spectral sensitivity based on the amino acid substitutions in the key tuning sites. Are absorption spectra of opsins tuned to match the light available in the environment? We localise and visualise the opsin gene expression in adult retinae via fluorescence in situ hybridization and discuss its functional consequences – namely if the presence of more opsins in the retina enhances colour vision or sensitivity of the visual apparatus. Finally, we present the latest results of single-nuclei RNA sequencing performed on the adult retina to reveal how individual cells utilise vision-related genes acquired by the polyploidization event.

Metabolic and physiological responses to genome duplication in duckweed: Linking polyploidy, size, and stress

Milosavljevic S^{1,2,3}, Mortier F^{1,2,3}, Bonte D³, Van de Peer Y^{1,2,4,5}

¹VIB - UGent Center For Plant Systems Biology, Ghent University, ²Department of Plant Biotechnology and Bioinformatics, Ghent University, ³Terrestrial Ecology Unit, Department of Biology, Ghent University, ⁴Department of Biochemistry, Genetics and Microbiology, University of Pretoria, ⁵College of Horticulture, Academy for Advanced Interdisciplinary Studies, Nanjing Agricultural University

POSTER SESSION 1 - **P01.152**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole genome duplication (WGD), or polyploidy, is a key evolutionary process that frequently alters plant physiology, morphology, and ecological responses. Though polyploid individuals arise commonly in nature, the successful establishment of polyploid populations remains rare. This paradox—frequent formation but infrequent persistence—raises important questions about the physiological and ecological consequences of genome duplication, particularly under environmental stress.

One consistent effect of WGD is increased cell and body size, which may modify a plant's metabolic rate and growth strategy. These changes could either confer tolerance to stress or impose unsustainable energetic demands, depending on context. Understanding how genome duplication affects metabolic traits and stress responses is essential for evaluating the ecological viability of polyploids and their potential to coexist or outcompete diploid progenitors.

In this study, we focus on *Spirodela polyrhiza*, an aquatic duckweed with rapid clonal growth and a well-characterized diploid background. We experimentally investigate how genome duplication influences size, biomass accumulation, and CO₂ exchange under salt stress, using a common garden approach across multiple genetic backgrounds. Our work builds on a prior study of neotetraploids derived via colchicine treatment, expanding the experimental design to nine diploid genotypes and their respective polyploids from three separate polyploidization events.

Each diploid–tetraploid pair was grown under a gradient of salt concentrations to simulate increasing osmotic stress. We measured fresh and dry biomass and recorded gas exchange data using the TARGAS-1 portable photosynthesis system and CO₂ consumption as a proxy for metabolic activity.

This expanded dataset allows us to assess not only the overall effects of genome duplication, but also how genetic background modulates those effects. Specifically, we ask whether neopolyploids consistently exhibit increased size, altered metabolic rates, or enhanced tolerance to salt, and whether these traits depend on genotype or stress level. We also evaluate whether gas exchange patterns scale with individual size or biomass-normalized activity.

Preliminary findings suggest that genome duplication leads to larger frond size and higher individual CO₂ assimilation, but not necessarily to improved salt tolerance. However, strain-specific responses and scaling patterns may reveal more complex genotype-by-ploidy interactions. These results will be presented and discussed in the context of eco-evolutionary dynamics and polyploid establishment theory.

By combining detailed physiological data across genotypes and stress conditions, this study provides a robust experimental test of theoretical predictions about polyploid performance. It also lays the foundation for future work linking size–metabolism relationships to the ecological success of polyploids in fluctuating environments.

Ploidy-dependent differences in mutation rate, spectrum and adaptive outcomes in *Chlamydomonas reinhardtii*

POSTER SESSION 1 - P01.139, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Mutation is the primary source of genetic variation and as such a prerequisite for evolutionary change. One of the most spectacular mutations, Whole genome duplication (WGD), has a high initial cost but is nevertheless ubiquitous within plants and is associated with evolutionary diversification and speciation. Classic population genetic models at the basis of our understanding of ploidy related differences in adaptation rate, often assume a duplication of the mutation rate, but studies on yeasts show that this assumption is overly simplistic and that, for instance, genetic background and heterozygosity can affect mutation rate. Despite the evolutionary importance of WGD in plants, the impact of WGD on the mutation rate and spectrum in the 'green lineage' is understudied. To address this gap, we conducted a mutation accumulation (MA) experiment with the

unicellular plant *Chlamydomonas reinhardtii*. Our study included 20 mutation accumulation lines from four haploid genotypes and 20 diploid mutation accumulation lines from four different genotypes with varying levels of heterozygosity. Over 14 months covering about 1000 mitotic generations, all 160 MA lines were grown under relaxed selection allowing the accumulation of all non-lethal mutations. The end points were sequenced and mutations were called. The results were integrated with fluorometry-based genome size measurements and data on the fitness evolution, and allow us to determine ploidy-related differences in mutation rate and spectrum including genomic (in)stability, aneuploidies, and the impact of heterozygosity, and ultimately, how these affect fitness.

Polyploidy in Action: Disentangling the Consequences of Genome Doubling in *Arabidopsis arenosa*

Petříková E¹, Clo J², Brindzák M¹, Nerandžičová D¹, Kolář F¹

¹Faculty of Science, Charles University, ²UMR EEP, University of Lille

POSTER SESSION 1 - P01.145, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole-genome duplication (WGD) is a key evolutionary process in flowering plants, often linked to changes in phenotype, life history, and stress responses. Yet, distinguishing immediate effects of genome doubling from traits shaped by long-term evolution remains challenging. *Arabidopsis arenosa*, which occurs naturally as diploid and tetraploid lineage, offers a valuable model. By comparing natural diploids, established tetraploids, and lab-induced neo-tetraploids, we aimed to separate the direct consequences of WGD from evolved features of stabilized polyploid lineages.

Using a common garden approach, we phenotyped a range of macroscopic, life-history, fitness, and cellular traits in the ancestral diploids and both tetraploid cytotypes. Neo-tetraploids produced bigger leaves but fewer flowers and marginally fewer but heavier seeds, indicating early trade-offs of WGD. Among cellular traits, endoreduplication (DNA replication without cell division) exhibited significant variation.

Its levels were similar in diploids and neo-tetraploids but significantly reduced in natural tetraploids, suggesting that the decrease in endoreduplication is not a direct effect of WGD but likely evolves over time under post-WGD selection.

To address whether WGD provides greater plasticity and evolvability, we exposed plants to drought stress in a short-term directional selection experiment. Rosette diameter and leaf area were significantly reduced across all cytotypes, while endoreduplication remained stable, reinforcing its role as a robust, non-plastic trait. To directly assess evolvability of the experimental populations, a second generation of plants is currently being grown under the same conditions, with the aim of quantifying trait shifts between generations using the breeder's equation. This approach will allow us to test whether WGD per se alters the evolutionary potential of plant populations in response to environmental stress.

Population genomic evidence of inter-ploidy gene flow in natural plant populations

Gerchen J¹

¹Charles University

POSTER SESSION 1 - **P01.155**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Polyploidy, the presence of multiple genome copies as a result of whole-genome duplications, is often thought to cause immediate reproductive isolation between diploids and related polyploids due to sterility and inviability of inter-ploidy offspring. However, cytological and population genetic evidence suggests that gene flow between plants with different ploidy levels (introgression) can happen in natural populations. Such inter-ploidy gene flow can happen either via production of viable gametes of triploid hybrids (triploid bridge) or, more commonly, via one-step gene flow mediated by unreduced gametes of a diploid. Recent research demonstrated first genomic and population genetic evidence consistent with hybridization and backcrossing in natural populations of diploid and tetraploid populations of multiple plant systems, challenging the paradigm of an impermeable ploidy barrier. Yet, it remains unclear how common such inter-ploidy introgression is and to what

degree it contributes to adaptation. Here we present preliminary evidence from multiple naturally occurring angiosperm lineages, where diploids and related autotetraploid lineages form one or multiple secondary contact zones. We use whole-genome resequencing data to detect evidence of inter-ploidy gene flow by using multiple population genomic analyses, which compare excess sharing of variation between diploids and tetraploids from the contact zones with populations from regions in which either only diploids or only tetraploids are located. Using this approach we test for genome-wide patterns of inter-ploidy gene flow. In addition, we identify local genomic patterns, with the aim to identify genomic regions where natural selection may favor or suppress inter-ploidy gene flow and ultimately test if such patterns are shared across lineages, in which polyploidy and secondary contact with diploids evolved independently.

Sex, behavior, and giant cells: missing elements of animal polyploid evolution with the parasitoid *Nasonia vitripennis*

Leung K¹, Sivaprakasham Murugesan S¹, Beukeboom L², Verhulst E¹

¹Wageningen University And Research, ²University of Groningen

POSTER SESSION 1 - **P01.149**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Ancestral whole genome duplication occurred in most eukaryotic lineages, with consequences at levels spanning individual physiology to adaptive advantage of species and populations. However, there are many gaps in the empirical study on animal polyploid evolution. This is because polyploidization, while challenging for all taxa, is especially detrimental for animals. They have severe immediate problems of cellular gigantism; sterility and gametic incompatibility; and disruptions to gene expression including sex dosage effects. These have limited research to single generations, or asexual lineages that can self-reproduce. We recently developed the sexual parasitoid wasp *Nasonia vitripennis* as a comprehensive model to overcome these barriers in animal polyploid study. An easy-to-maintain system, polyploids can reliably be induced with meiotic inhibition or gene silencing of various targets in the sex determination pathway. Importantly and exceptionally, *Nasonia* polyploids of both sexes are reproductive, enabling continuous study through generations. Extensive foreknowledge of the *Nasonia* system also allows for more complex contextualization of animal polyploidy. Our studies are the first indication of sexual tradeoffs in polyploid evolution, as lines that exhibit high male

reproductive success (mate acceptance and offspring production) correspondingly have low female reproductive success (offspring production), and vice versa. Complicating this is the influence of behavior, with strong female mate choice possibly discriminating against impaired polyploid males, so inhibiting inheritance of the polyploid state. One suspect factor is somatic endopolyploidy: regional giant, multinucleated cells obligate to normal development. How aberrant organismal polyploidization (e.g., its own cell gigantism effects) impacts endopolyploidy is largely unknown, but *Nasonia* males have endopolyploid wings key to courtship success. The retention of endopolyploidy is inconsistent in polyploid males, likely correlating to their varying mating success. And yet, *Nasonia* males also have sneaking behavior, allowing disadvantaged polyploid males to benefit from non-polyploid male signals and enhance their mating success. This highlights the need to examine behavioral interactions for their contribution the evolutionary successes and failures of polyploid lineages. This collective research in the *Nasonia* model reflects a new phase of animal polyploid evolution study accounting for interrelated roles of sex, behavior, and endopolyploidy.

Single-cell sequencing suggests a conserved function of Hedgehog-signaling in spider eye development

Medina Jiménez B^{1,2}, Budd G², Pechmann M³, Posnien N⁴, Janssen R²

¹Department of Zoology, Stockholm University, ²Department of Earth Sciences, Uppsala University,

³Department of Developmental Biology, University of Cologne, ⁴Department of Developmental Biology, University of Göttingen

POSTER SESSION 1 - P01.138, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Spiders evolved different types of eyes, a pair of primary eyes that are usually forward pointing, and three pairs of secondary eyes that are typically situated more posterior and lateral on the spider's head. The best understanding of arthropod eye development comes from the vinegar fly *Drosophila melanogaster*, the main arthropod model organism, that also evolved different types of eyes, the larval eyes and the ocelli and compound eyes of the imago. The gene regulatory networks that underlie eye development in this species are well investigated revealing a conserved core network, but also show several differences between the different types of eyes. Recent candidate gene approaches identified a number of conserved genes in arthropod eye development, but also revealed crucial differences including the apparent lack of some key factors in some groups of arthropods, including spiders.

Materials and Methods: Parasteatoda tepidariorum embryos at mid-late developmental stages were processed for single-cell RNA sequencing following the 10x Genomics Single Cell 3' protocol at the Department of Developmental Biology and Gene Core facilities of the European Molecular Biology Laboratory, Heidelberg, Germany. Sequencing reads were mapped to the reference genome using 10x Cell Ranger pipelines and the resulting gene expression matrix was analysed with the bioinformatic tool 'Seurat'. Cell clustering was validated via in situ hybridisation and Gene Ontology analysis. Embryos of related spider species (namely, *Acanthoscurria geniculata*, *Ischnothele caudata*, *Pholcus phalangioides*, and *Pardosa amentata*) and the harvestman *Phalangium opilio* were fixed and used for in situ hybridisation to visualize the expression patterns

of hedgehog orthologs and selected gene markers that were found in the scRNA data. Sequence alignment and Phylogenetic analysis were performed using T-coffee and Mr. Bayes, respectively.

Results: Here, we re-analysed our published scRNA sequencing data (Medina-Jiménez et al. (2024) Single-cell RNA sequencing of mid-to-late stage spider embryos: new insights into spider development) and found potential key regulators of spider eye development that were previously overlooked. Unlike earlier research on this topic, our new data suggest that Hedgehog (Hh)-signalling is involved in eye development in the spider *Parasteatoda tepidariorum* via a second paralog (hh2). By investigating embryonic gene expression in representatives of all main groups of spiders, we demonstrate that this involvement is conserved in spiders. The most likely scenario in spiders is that the two copies of hedgehog have undergone sub-functionalization after a duplication that occurred in the lineage leading to Arachnopolmonata (i.e. scorpions, whip spiders, and spiders), and indeed similar cases of sub-functionalization in spiders have been recorded frequently (e.g. Schwager et al., 2017; Leite et al, 2018; Janssen et al., 2021; Aase-Remedios et al., 2023).

Additionally, we identified genes that are expressed in the developing eyes of spiders, but that have not been studied in this context before. **Conclusion:** Our data show that single-cell sequencing represents a powerful method to gain deeper insight into gene regulatory networks that underlie the development of lineage-specific organs such as the derived set of eyes in spiders. Overall, we gained deeper insight into spider eye development, as well as the evolution of arthropod visual system formation.

The phased genome assembly of *Xenopus mellotropicalis* sheds light on the pace of subgenome dominance and diploidization in animal polyploids

LIZ¹, Clavereau I¹, Pollet N¹

¹Université Paris-Saclay, CNRS, IRD, UMR Évolution, Génomes, Comportement et Écologie

POSTER SESSION 1 - **P01.148**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Polyploidization plays a significant role in driving macroevolution. Yet, its evolutionary consequences remain poorly understood in animals, where polyploidy is rare, understudied and often rapidly followed by rediploidization. In frogs, *Xenopus* is one of the few genera with widespread polyploidization, with species ranging from diploid ($2n = 2x$) to dodecaploid ($2n = 12x$). We present a high-quality, phased genome assembly of the tetraploid frog *Xenopus mellotropicalis*, constructed from Nanopore, Illumina, and Hi-C sequencing reads. The 2.98 Gbp genome comprises 20 chromosomes, with a BUSCO completeness score of 97.2% (88.9% duplication), a scaffold N50 of 157 Mbp, and a contig N50 of 914 Kbp. Using k-mer analysis, we successfully phased the two subgenomes. Gene and transposable element (TE) annotations revealed that subgenome A harbours more genes and fewer TEs than subgenome B. Expression profiling showed higher expression in subgenome A,

consistent with ongoing subgenome dominance. Kimura divergence of ohnologue pairs suggests a recent polyploidization event (~ 9 million years ago), classifying *X. mellotropicalis* as a neopolyploid. Gene and genome comparison between the *X. mellotropicalis* and the diploid *Xenopus tropicalis* revealed that both subgenomes are highly syntenic with *X. tropicalis*. Interestingly, genes from subgenome B are phylogenetically closer to *X. tropicalis*, though about one-third of genes show the opposite pattern. This indicates that homoeologous exchange might occur during its diploidization, contrasting with previous observations in the allotetraploid *Xenopus laevis*, where homoeologous exchanges are scarce. Our results provide new insights into diploidization and subgenome evolution in animal polyploids, highlighting *X. mellotropicalis* as a valuable model for studying genome evolution after a relatively recent allopolyploidization.

Transposable Elements as Drivers of Regulatory and Genomic Innovation in Spiders

Erdoğan D^{1,2}, Turetzek N², Posnien N¹

¹Department of Developmental Biology, Göttingen Center for Molecular Biosciences (GZMB), University of Göttingen, ²Evolutionary Ecology, Faculty of Biology, Biocenter, Ludwig-Maximilians-University of Munich

POSTER SESSION 1 - P01.153, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Gene and genome duplications provide new raw material for novel gene functions and regulatory networks and are thus key mechanisms of evolutionary diversification. Recent comparative genomics analyses suggest a large-scale or even whole-genome duplication event in the common ancestor of spiders and scorpions, which could have set the stage for spider-specific innovations, such as silk and venom production, as well as specialized respiratory systems. Despite growing interest, the molecular mechanisms shaping expression and regulatory divergence after duplication remain poorly understood in arthropods.

Transposable elements (TEs)—mobile repetitive sequences known to influence genome architecture and regulation—have been shown to play a role in gene expression divergence following duplication events. To link TEs to gene duplication diversification in spiders, we established curated TE libraries for 24 chelicerate species, including spiders, scorpions, and ticks. We show that constructing species-specific TE libraries are essential to obtain reliable TE annotations and to infer TE activities through evolutionary time. Using our curated libraries, we investigated the relationship between repeat content and gene architecture, revealing a strong positive correlation between intron length and TE occupancy—suggesting that transposable element (TE) accumulation contributes to intron expansion. Since

introns often contain regulatory information, we hypothesized that intron expansion could provide a substrate for regulatory divergence between gene duplicates. We are testing this hypothesis by integrating the occurrence of intronic TEs with functional genomics data for the two distantly related spider species *Parasteatoda tepidariorum* and *Ischnothele caudata* to assess gene regulation (ATAC-seq) and gene expression (RNA-seq) between duplicated genes. In addition to their presence in non-coding regions, TEs can also be exonized to contribute to divergence on the protein level. A preliminary analysis identified more than 3400 TE-derived distinct exonic sequences in a spider, pointing to a potentially significant contribution of TEs to coding sequence evolution. While exonized TEs have been documented in vertebrates, there is a notable lack of systematic investigation into their role in arthropods, making these findings a promising starting point for future exploration in this group.

In summary, our data demonstrates the value of tailored TE annotation strategies for non-model species, enabling high confidence downstream analyses of TE distribution, function, and evolutionary relevance. We employ our spider-specific TE annotations to link TE activity to diversification of gene regulation and protein evolution after gene duplication.

Zombie Gene Flow: Asexual Polyploid Hybrids Reintroduce Genomic Elements of Extinct Species into Contemporary Sexual Populations

Janko K¹, Vukic J², **Andjel L**, Dedukh D¹

¹Institute of Animal Physiology and Genetics, ²Department of Ecology, Charles University

POSTER SESSION 1 - **P01.158**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Whole genome duplications (WGD) and hybridization are widely recognized as potent drivers of evolutionary novelty, often linked to bursts of species diversification, genomic innovation, and adaptation. However, prevailing paradigms largely focus on sexually reproducing taxa, assuming that interspecific gene flow requires fertile, recombining hybrids to transmit alleles between gene pools. Hybrids with non-standard reproductive modes, such as clonal or odd-ploidy forms, are typically viewed as evolutionary dead ends.

Here, we challenge this view by presenting the first fully documented case of gene flow from an extinct species into an extant sexual lineage, mediated not by meiotic recombination, but by asexual, polyploid hybrids. Using cytogenetic, experimental, and phylogenomic data, we show how asexual diploid-triploid hybrids in *Cobitis loaches* act as “zombie gene flow” vectors, reintroducing long-lost genomic elements from extinct ancestors into contemporary sexual populations.

Specifically, we uncover how ancient hybridization between the now-extinct sexual species (“X”) and the extant *Cobitis ohridana* (“O”) gave rise to diploid (OX) and triploid (OOX) hybrids, which differ sharply in reproductive strategy. Diploid OX hybrids reproduce mostly clonally, preserving the X genome intact over evolutionary time. However, occasional gene conversion events ingress X-alleles onto O-genomic background. By contrast, triploid OOX hybrids systematically eliminate the X genome during gametogenesis, but generate reduced gametes by recombining O chromosomes, allowing them to backcross with sexual *C. ohridana*. This ploidy-dependent oscillation between clonal maintenance and sexual recombination enables substantial gene flow from the extinct X lineage into the

contemporary O gene pool, resulting in over 4% genomic admixture detectable in nuclear and mitochondrial compartments of modern *C. ohridana*.

Importantly, while our system offers the first full empirical demonstration of “zombie gene flow,” its mechanistic components—clonal maintenance, ploidy variation, occasional rediploidization, and cryptic recombination—are shared across diverse taxa, including fish, amphibians, insects, and plants. This suggests that polyploid hybrid systems worldwide may harbor a hidden capacity to preserve and reintroduce ancient genetic material, reshaping our understanding of WGD’s role in macroevolutionary dynamics.

Our work also touches on key themes in the study of genome evolution: the long-term retention of duplicated genomic material, shifts in gene expression regulation following hybridization and WGD, and the evolutionary consequences of genome rearrangement and rediploidization. Notably, we highlight how hybrid asexuals can act as cryptic reservoirs of genomic variation, challenging assumptions about the permanence of extinction and offering new insights into how WGD and polyploidy can shape the genetic architecture of biodiversity.

Finally, we emphasize the conservation implications of our findings. As global species loss accelerates, recognizing the evolutionary potential of hybrid asexuals to preserve genetic legacies from extinct taxa opens new avenues for biodiversity conservation and management. By integrating cytogenetics, experimental crosses, and comparative genomics, our study not only redefines the evolutionary roles of polyploidy and asexuality but also calls for a broader, integrative framework to capture the hidden contributions of WGDs to long-term evolutionary resilience.

Breaking the ploidy barrier: Genomic insights into allopolyploidy and cross-ploidy hybridisation in British plant genus *Euphrasia* (eyebrights).

Davies E^{1,2}, Blaxter M³, Hollingsworth P², Twyford A^{1,2}

¹University Of Edinburgh, ²Royal Botanic Garden Edinburgh, ³Wellcome Sanger Institute

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Polyploidy, or whole genome duplication (WGD), has long been recognised as an important driver of speciation, as it is widely assumed to cause instantaneous reproductive isolation between newly formed polyploids and their diploid progenitors. However, recent research has increasingly documented cross-ploidy hybridisation across a range of taxa, highlighting the potential of interploidy hybridisation to shape evolutionary outcomes. In this study, I investigate the role of cross-ploidy hybridisation in British native *Euphrasia* (eyebrights), a genus of diploids and tetraploids that frequently hybridise. Using one of the first high quality polyploid reference genome from the Darwin Tree of Life project—which is generating reference genomes for all eukaryotic species in Britain and Ireland—I show polyploid *Euphrasia* are

allopolyploid in origin, with divergent subgenomes. Using genome resequencing data from 118 diploid and tetraploid *Euphrasia* samples, I show subgenome A is genetically divergent from extant diploid *Euphrasia* species while subgenome B shows genetic similarity to existing diploids. Preliminary sequence comparisons of these diploid and tetraploid populations reveal clear groupings according to ploidy, but notably there are some intermediate individuals consistent with rare cases of interploidy gene flow. These results underscore the evolutionary potential of interploidy hybridisation, with future work to assess whether adaptive introgression occurs repeatedly across a ploidy barrier and underlies the origin of the cross ploidy hybrid species *Euphrasia vigursii*.

Consequences of whole-genome duplication on expansion and adaptation to environmental heterogeneity in *Biscutella laevigata*

Grünig S^{1,2}, Choudhury R¹, Beringer M^{1,2}, Parisod C^{1,2}

¹Department of Biology, University of Fribourg, ²Institute of Plant Sciences, University of Bern

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Whole-genome duplication (WGD) is a major driver of plant speciation and often considered to promote rapid adaptation to new or changing environmental conditions. However, the extent to which WGD per se fosters phenotypic novelties, how diploids vs polyploids respond to selection, and how long-term evolution act on WGD-induced changes remain unclear. To investigate those long-standing questions, the *Biscutella laevigata* textbook example of mixed-ploidy system is a great model. Climatic niche modelling together with spatial genetics and coalescent modelling highlighted that diploids restricted to never-glaciated lowlands were pushed out of the Alps during the Pleistocene and differentiated for the last 100 KY, whereas tetraploids occurring at high-elevation in previously-glaciated areas were formed before the last glacial maximum (ca. 25 KY ago) from a single diploid population and then recolonized the Alps. Tetraploids display tetrasomic inheritance and occupy similar environmental niche as their diploid progenitors, indicating autopolyploidy (or WGD s.str).

To characterize the relative contribution of WGD per se vs post-WGD evolution to phenotypic and transcriptomic changes, our work compared diploid, synthetic tetraploid and established tetraploid lines of *B. laevigata*, assessing phenotypic plasticity and stress resilience following growth under either stable or changing conditions (i.e. involving a daily temperature stress). While WGD directly induced some phenotypic changes, transcriptional changes were driven by subsequent evolution rather than by WGD itself. Post-WGD evolution indeed modulated WGD-induced phenotypic changes by either reverting them toward diploid-like values or

maintaining them. Finally, WGD led to a reduction of survival and fitness, which was mitigated by post-WGD evolution, resulting in established tetraploids with similar or even higher fitness under changing environmental conditions than diploids, suggesting that adaptive changes evolved following WGD.

To further assess whether genomic and phenotypic variation reflects adaptation following whole-genome duplication, and to investigate how diploids and tetraploids respond to selection, which remains uncharacterized, we combined whole-genome sequence data and transplant experiments of diploid and autotetraploid populations sampled at low and high elevation in a factorial design. Tetraploids showed higher non-synonymous genomic variation, consistent with relaxed purifying selection, and a higher proportion of candidate loci associated with adaptation to elevation than diploids. Diploids indeed presented considerable plasticity maintaining fitness homeostasis across elevation, whereas tetraploids showed genetically based fitness variation and phenotypic signatures of adaptation to elevation, suggesting that genomic variation accumulated after WGD enhanced the adaptive potential of tetraploids under environmental changes.

Together, these findings highlight the important role of post-WGD evolution in driving phenotypic and transcriptomic changes. This suggests that WGD is not an inherent driver of adaptation per se, but rather promotes reproductive isolation from progenitors and, supporting the accumulation of high genomic variation, further promotes response to selection in tetraploids that can hence adaptively diverge from diploids.

Evidence of lineage-specific rediploidisation after whole genome duplication in vertebrate ancestor

Niezabitowski L¹, Long R¹, Redmond A², McLysaght A¹

¹Trinity College Dublin, ²University College Dublin

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Background: All vertebrate genomes are impacted by multiple rounds of ancestral polyploidisation that have shaped their structure, organisation, and function. Genes arising from these events, termed ohnologs, amount to 20-35% of the human genome and have played a major role in the evolution of vertebrate complexity, development, and susceptibility to genetic disease.

Following whole genome duplication (WGD), chromosomes follow tetrasomic inheritance patterns whereby recombination between homeologous chromosomes is random and equally likely, preventing the divergence of duplicate gene sequences. Thus, any individual gene cannot be considered 'duplicated' until recombination is suppressed. Chromosomes eventually revert to a diploid state in a gradual and asynchronous process termed delayed rediploidisation. Rediploidisation proceeds over a timescale of millions of years and, when overlapping with speciation events, can result in a large number of lineage-specific duplicates, potentially giving rise to unique biological functions.

Previous work found no evidence of delayed rediploidisation after 1R in gnathostomes (jawed) and cyclostomes (jawless vertebrates) and only to a limited extent after the cyclostome-specific genome triplication. However, this work did not account for the GC bias observed in cyclostome genomes, which is well known to cause artefacts in phylogenetic analysis.

Materials and methods: In this study, we re-annotate hox clusters and hox-flanking genes in two hagfish and three lamprey genomes. Using these together with hox clusters from five gnathostome genomes, we build phylogenetic trees based on hox cluster

alignments and classify them according to their rediploidisation timing relative to the cyclostome-gnathostome split. By varying the number of composition vectors in our phylogenetic models, we investigate the effect of composition bias on tree topology. Furthermore, we identify other genomic regions that experienced delayed rediploidisation using a novel macro-synteny-based approach.

Results: When accounting for composition bias, our analysis shows evidence of delayed rediploidisation in hox cluster regions following both 1R and the cyclostome-specific genome triplication. These observations are consistent regardless of technical differences in methodology, such as alignment method or choice of outgroup. Furthermore, we identify other 1R ohnologs and classify them based on divergence time. When mapped onto cyclostome and gnathostome genomes, these genes form distinct pre- and post-speciation clusters on most vertebrate chromosomes, suggesting a widespread impact of delayed rediploidisation on vertebrate genomes.

Conclusions: We show evidence of extensive lineage-specific rediploidisation in cyclostomes and gnathostomes following the vertebrate 1R while highlighting the importance of correctly modelling compositional heterogeneity in these lineages. The mosaic of shared and lineage-specific gene duplications across cyclostome and gnathostome chromosomes suggests a large capacity for lineage-specific adaptations, which may have contributed substantially to the unique biological innovations of each lineage. Our work has major implications for our understanding of vertebrate genome evolution and adaptation following early vertebrate whole genome duplication events.

Evolution of Gene Content and Expression Following Various Whole Genome Duplication Events in Vertebrates

Montfort J¹, Hervas-sotomayor F¹, Le Cam A¹, **Murat F¹**

¹INRAE / LPGP

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

A fundamental question in biology is to better understand the molecular bases of phenotypic evolution. Gene and genome duplications, followed by structural and functional rearrangements, are believed to underlie many molecular and phenotypic differences across species, probably contributing to the emergence or modification of tissues and cell types over evolution. Vertebrates offer a unique opportunity to study this phenomenon as they underwent several Whole Genome Duplication events (WGD) at different timescales, providing new raw genetic material for evolutionary forces to act on. Notably, these WGDs have since been followed by extensive genomic and functional reshuffling aimed at reducing redundancy through a process known as rediploidization, likely facilitating the diversification of species, organs, and cell types. In addition, vertebrates exhibit an outstanding phenotypic diversity. In this study, we use large-scale comparative genomics and transcriptomics to explore the evolution of gene content and expression after various WGDs at different timescales across vertebrates. We focused on key WGDs such as the jawed-vertebrate (2R), the teleost-specific (Ts3R), the salmonid-specific (Ss4R) and the carp-specific (Cs4R) ones that occurred approximately 500 mya, 300 mya, 100 mya and 20 mya, respectively. Overall, our work dissected rediploidization processes at both structural and expression levels. Notably, we modeled gene loss trajectories across 160 vertebrate species following WGD events and showed that in addition to the occurrence of WGDs, the rediploidization phenomenon plays a central role in the gene content of extant genomes. We also demonstrated that rediploidization does not occur linearly over evolutionary time, as gene loss is initially massive following WGDs and gradually diminishes, stabilizing at a 'canonical' number of genes in vertebrates. We showed that the initial wave of rediploidization,

driven by extensive gene loss, accelerates genome divergence by proceeding in a lineage-specific manner, thereby reinforcing the role of WGDs as catalysts of evolutionary innovation. Cross-species comparisons of RNA-seq data from seven organs across twelve representative species revealed that duplicated genes are more tissue-specific than singletons. Moreover, the degree of tissue specificity increases with the number of gene copies, confirming that tissue specialization tends to follow gene duplication in fish, whether they underwent ancient or more recent WGDs. However, we also observed that duplicates in recently duplicated genomes are less tissue-specific than those in anciently duplicated genomes, suggesting that tissue specialization generally occurs progressively after genome duplication. To explain this pattern, we proposed and confirmed two non-mutually exclusive scenarios. First, we found that the enhanced tissue specificity observed in anciently duplicated genomes is partly due to the preferential loss of broadly expressed duplicates, leading to the retention of more tissue-specific ones. Second, we observed that differences in tissue specificity are more pronounced among duplicates from anciently duplicated genomes, suggesting that these genes have had more time to accumulate regulatory mutations and develop divergent expression patterns, resulting in greater specialization compared to their paralogs. In conclusion, the results of this study demonstrate the substantial impact of WGDs and subsequent rediploidization processes on gene content and expression in extant vertebrate genomes, likely contributing to the emergence and diversification of tissues and cell types over evolution. We are now applying recently developed cell-focused technologies across species and fast-evolving organs, such as the gonads, to further investigate the role of gene and genome duplications in organ and cell type diversification across species.

Evolution of Regulatory Elements Following Autopolyploidization in Salmonid Fish

GUNDAPPA M^{1,2}, Lien S³, Macqueen D²

¹Wageningen University And Research, ²The Roslin Institute, University of Edinburgh, ³Centre for Integrative Genetics (CIGENE), Norwegian University of Life Sciences

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Background: Whole genome duplication (WGD) is a widespread phenomenon in plant and animal evolution and has been associated with phenotypic diversification and evolutionary innovation. Approximately 100 million years ago, the common ancestor of salmonids experienced a lineage-specific WGD by autopolyploidization, with a substantial proportion of the duplicated genome still retained. This makes salmonids an ideal vertebrate model for studying the impacts of autopolyploidization on genome and regulatory evolution. Beyond gene expression, understanding the evolution of regulatory elements which govern the spatial and temporal patterns of gene activity is crucial to translate the phenotypic outcomes of WGD. In this study, we leverage the extensive functional annotation resources generated by the European AQUA-FAANG project, including over 600 million ATAC-Seq and 4,000 million ChIP-Seq reads, to investigate the fate of duplicated regulatory elements in the genomes of Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*). Our primary objective was to assess the conservation and evolution of regulatory element activity across ontogeny and link these patterns to the salmonid-specific WGD event.

Materials and Methods: We generated duplicate-aware whole genome alignments of Atlantic salmon and rainbow trout using Cactus, enabling the accurate alignment of duplicated syntenic regions. Northern pike (*Esox lucius*) was included as an outgroup to infer the ancestral genome state prior to WGD. High-confidence ATAC-Seq peaks from multiple embryonic stages and six adult tissues at two stages of sexual maturation were intersected with the alignments to assess regulatory element activity. We then investigated the coupling between sequence conservation and regulatory element activity across open chromatin regions in duplicated segments. Duplicated promoter and enhancer conservation across developmental stages was systematically analyzed to identify evolutionary constraints.

Furthermore, conserved non-coding elements (CNEs) of varying evolutionary ages were overlapped with identified promoter and enhancer elements to understand conservation of genome regulation across taxa. Lastly, we compared regulatory element conservation between genomic regions with early and late rediploidization histories to infer post-WGD evolutionary dynamics.

Results: Our genome alignments captured a high proportion of duplicated and orthologous sequences across Atlantic salmon, rainbow trout, and northern pike, validating the robustness of our approach. We observed that the proportion of active enhancers retained across duplicated regions increased through embryogenesis, peaking during late somitogenesis. In adult tissues, conservation was highest in the brain and lowest in the testis, with similar trends seen in promoter elements. CNEs of the deepest evolutionary origin were significantly enriched during late embryonic development in ontogeny and in the brain, highlighting the role of ancient regulatory elements in shaping genome function. Our findings highlight the utility of synteny aware genome alignments in elucidating the evolutionary dynamics of regulatory elements post-WGD. The outcomes also broadly align with the developmental hourglass model, demonstrating that regulatory conservation is strongest during the phylotypic stage, extending previous observations into the context of whole genome duplication.

Conclusion: This study provides a detailed functional annotation of two salmonid species and offers a comprehensive analysis of regulatory element evolution following autopolyploidization. Our findings enhance our understanding of how regulatory element activity is linked to ontogeny following WGD, offering important insights into vertebrate genome evolution.

Is there an advantage to polyploidy in animals? *C. elegans* neotetraploids resist severe cold by escaping cold induced death as gravid adults.

Chauve L¹, Bazzani E, Verdier C, Butler L, McGarry A, Mclysaght A

¹Trinity College Dublin

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Gene duplications play a key evolutionary role by providing raw material for functional innovation. Whole Genome Duplication (WGD), or polyploidisation, is a particular case of duplication in which the entire genetic sequence is repeated within the nucleus. In plants, WGD is recognised as a major evolutionary force, and is linked to speciation and the ability to resist periods of stress and of environmental upheaval.

In animals, examples of current polyploid species are rarer, although several ancient WGD events are well documented: for instance, two rounds of WGD occurred during early vertebrate evolution. These events are typically followed by gene loss and rediploidisation, processes that reshape genomes and influence evolutionary trajectories. However, the reasons behind the successful establishment of polyploid animal species remain unclear. While WGD can arise in response to stress, a debated hypothesis suggests that polyploidy may confer selective advantages under stressful conditions, potentially outweighing early fitness costs such as reduced fertility.

Our aim is to investigate the immediate physiological and stress-related consequences of polyploidy and its potential adaptive value in animals. We are using *Caenorhabditis elegans*, where tetraploidy can be experimentally induced via transient knockdown of *rec-8*, a component of the cohesin complex.

Our results show that while tetraploidy reduces fitness, under regular conditions,

marked by lower fertility and reduced lifespan, tetraploid animals exhibit increased resistance under specific stress conditions, related to temperature changes. While tetraploids exhibit similar pathogen resistance, their response to heat stress is slightly increased. Remarkably, when exposed to severe cold stress followed by recovery, gravid neotetraploid animals massively escape cold-induced death. Additionally, upon cold stress recovery, neotetraploids produce more progeny of comparable quality, suggesting a potential adaptive value.

We investigated whether established mechanisms linked to cold-induced death in gravid diploids operate differently in tetraploids. Previous studies had linked cold-induced death with intestine-to-gonad lipid relocalisation, and to the activation of a cold-triggered genetic death program involving the transcription factor *zip-10*. Our lipid localisation analysis (presented in another poster from the lab) suggests that improved cold survival in tetraploids is not due to defective lipid trafficking. We also found reduced induction of the *zip-10* mediated death program in cold shocked tetraploids although this could only partially account for their improved survival.

Overall, our findings suggest that polyploidy may provide advantages under extreme cold stress and point to novel mechanisms underlying tetraploid resilience to cold-induced death.

Structural variation and dysploidy shape drought responsive gene landscapes in *Nicotiana* sect. *Suaveolentes*

Cauz dos Santos L¹, Moser L¹, Leitch A², Chase M³, Paun O¹

¹University of Vienna, ²Queen Mary University of London, ³Royal Botanic Gardens, Kew,

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Whole genome duplication (WGD) provides genetic redundancy that can foster novel adaptations, yet its aftermath, marked by structural variation (SV) and descending dysploidy, remains underexplored in adaptive radiations. These rearrangements reconfigure chromosome architecture, linkage associations, and recombination patterns, potentially clustering or dispersing environment responsive loci. Darlington's chromosome condensation hypothesis proposes that progressive dysploidy physically links co adaptive genes into advantageous blocks, enhancing resilience under stress. To test this idea, we focused on *Nicotiana* section *Suaveolentes*, an allotetraploid clade that arose ca. 6 Mya and subsequently lost chromosomes in a dysploid series ($n = 24 - 15$), coincident with an explosive radiation across Australia. Remarkably, many low count taxa now thrive in the continent's most arid interiors despite retaining thin, herbaceous leaves. Here, we assessed whether drought responsive genes in arid versus mesic lineages are preferentially shielded from structural variants or, instead, concentrated within rearranged genomic regions. For this purpose, we selected two species pairs: the arid adapted *N. velutina* ($n = 16$) vs. its mesic sister *N. gossei* ($n = 18$), and the arid adapted *N. truncata* ($n = 18$) vs. mesic *N. excelsior* ($n = 20$). We generated high quality draft assemblies for both arid taxa: *N. velutina* assembled into 395 contigs (2.71 Gb; N50 = 132 Mb, L90 = 21), and *N. truncata* assembled into 1004 contigs (3.15 Gb; N50 = 122 Mb, L90 = 26). In parallel, we conducted drought experiments on both species pairs: plants were either well watered or subjected to ten days without water then rehydrated 24 h before sampling. Leaf and root tissues

were harvested for RNA seq and analyzed for differential expression (DE). We identified 1 268 and 782 drought responsive genes in leaves and roots of *N. velutina*, and 917 and 1 218 in *N. gossei*. In the second pair, *N. excelsior* yielded 955 leaf and 705 root DE genes, while *N. truncata* showed 1 899 leaf and 1 262 root DE genes. Independently, long reads from each mesic species were aligned to its arid sister's genome to discover SVs, and after excluding ambiguous breakends, we retained over 400 000 high confidence SV events per pair, predominantly deletions and insertions with a minor fraction of inversions. Our key analyses compared the proportion of drought responsive genes that overlap SV regions versus the genomic background. In the *velutina*–*gossei* pair, the arid *N. velutina* showed a significant depletion of drought genes in SV regions (85.3 % overlap vs. 87.8 % background; $p = 0.0082$), consistent with insulation of key loci from rearrangement. Its mesic sister *N. gossei* was neutral (86.5 % vs. 87.8 %; $p = 0.223$). In the *truncata*–*excelsior* pair, mesic *N. excelsior* leaves exhibited enrichment of DE genes in SVs (92.6 % vs. 90.1 %; $p = 0.0076$); arid *N. truncata* leaves were neutral (90.9 % vs. 90.1 %; $p = 0.199$). Across all four species, inversions accounted for > 90 % of these overlaps, but only ca. 20 % of DE genes lay exclusively within inversion intervals. These results offer an empirical validation of Darlington's chromosome condensation hypothesis in a post WGD plant radiation. They reveal that descending dysploidy and SV can either insulate or cluster environment responsive genes in a lineage and tissue specific manner, shaping the genomic architecture that underpins rapid ecological adaptation and speciation in *Nicotiana* section *Suaveolentes*.

The genome evolution of young autopolyploids and their rediploidization

Xu L¹, Xie C¹, Liu H¹

¹Southwest University

MEETING ROOM 118+119, August 18, 2025, 2:00 PM - 5:00 PM

Whole genome duplication (WGD) and subsequent rediploidization were ancient, rare, and fundamental evolutionary events that shaped the genomes in early vertebrates. But the dynamics and patterns of these ancient rediploidizations are difficult to investigate. A group of young polyploid fish adapted to living at high altitudes, the snow carp (subfamily Schizothoracine), provides the opportunity to study recent repeated evolution of autopolyploidization that is then followed by re-diploidization. Genomic data from all eleven snow carp genera demonstrate that they are autopolyploid, including tetraploids, hexaploids and rare icosaploids (20n). Using improved bioinformatic approaches, we generated a fully phased chromosome-level genome for *S. younghusbandi* (4n = 90), one of the most specialized snow carp. Comparative genomic analyses identified five unbalanced chromosomal fusions between subgenomes. Further studies of

meiotic karyotypes and sequence divergence suggest only those fused chromosomes evolved disomic inheritance (rediploidization), while the unfused chromosomes remain tetrasomic. Rediploidization was initiated around the fusion points, gradually expanding outwards towards chromosomal arms. We detected signals of biased gene losses on the fused chromosomes, suggesting subgenome dominance driven by chromosomal fusions. Genes with divergent expression on the rediploidized regions, such as *GPX4*, have likely contributed to the adaptation to the extreme conditions of the Qinghai-Tibetan Plateau. We show that all snow carp lineages shared a specific fourth round of WGD (ScR4), followed by lineage-specific rediploidization. Our analyses of the haplotype-resolved snow carp genome highlight the importance of chromosomal fusions in the early evolution of young vertebrate autopolyploids.

A systematic review of hybridization dynamics in frogs: Associations with breeding patterns and courtship behavior

Gomes T¹, Mozer L¹, Belasen A², Zamudio K², **Nali R**¹

¹Universidade Federal de Juiz de Fora, ²University of Texas at Austin

POSTER SESSION 1 - P01.182, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Hybridization can influence evolutionary trajectories across the tree of life, yet the role of specific reproductive strategies in facilitating or constraining hybridization within animal groups remains underexplored. For instance, frogs exhibit two distinct temporal breeding patterns: explosive breeding, with brief, high-density aggregations and minimal mate selection; and prolonged breeding, with extended reproduction involving mate choice and, at times, elaborate courtship behaviors that may prevent interbreeding. Hybridization is assumed to be more common in explosive breeders without courtship, but the absence of a systematic review limits our understanding of its dynamics in this diverse and threatened order. We conducted a systematic literature review to assess the distribution of hybridization across frog families and genera, and to determine (1) whether hybridization is more frequent in explosive breeders, and (2) whether these species consistently lack courtship compared to prolonged breeders, potentially facilitating interbreeding and hybridization.

Materials and methods: Following the PRISMA protocol, we searched Google Scholar and Web of Science for articles published between 1950 and 2024 using keywords such as 'Anura', 'Hybridization', 'Introgression', 'Explosive breeding', 'Prolonged breeding', and 'Courtship'. We first removed duplicates and screened titles and abstracts to exclude irrelevant studies. We then assessed the remaining full-text articles for eligibility, excluding those that were inaccessible. Additionally, we identified further records through citation searching and excluded those that did not meet eligibility requirements according to PRISMA. We visualized the data and performed Fisher's exact tests to assess the association between courtship and breeding patterns in known hybridization cases in frogs.

Results: We identified 1,801 articles in Google Scholar and Web of Science, and 92 additional articles via citation searching. After initial

screening, 166 articles qualified for full-text review, with 129 meeting inclusion criteria for the final analysis. We identified 88 cases of frog hybridization in 36 genera across 15 families. Of all cases, 50% involved explosive breeders, predominantly in the true toads (Bufonidae), 28% involved prolonged breeders, predominantly within the true tree frogs (Hylidae), and 9% involved one explosive and one prolonged breeder. Breeding patterns were unknown for species in 13% of the cases. Among explosive breeders, courtship was undocumented in 43 cases of hybridization and documented in one. In prolonged breeders, 21 cases lacked documented courtship, while four exhibited courtship behavior. The association between courtship and reproductive patterns in hybridization cases was marginally non-significant, with prolonged breeders tending to exhibit a higher proportion of documented courtships compared to explosive breeders.

Conclusions: Our review indicates that hybridization is widespread in frogs, but the high prevalence in two well-studied families suggests uneven research focus, potentially biasing conclusions about its overall frequency. We corroborated that hybridization is more frequent in explosive breeders, but its occurrence in prolonged breeders, in which courtship was more frequently documented, was substantial enough to challenge the assumption that mate selection and courtship are enough to reinforce species boundaries. Our data suggests that isolation in frogs is more complex than previously thought, with alternative reproductive tactics, such as satellite males, potentially contributing to hybridization. This study underscores the role of reproductive behaviors in shaping species boundaries and evolution, emphasizing the need for integrative research in behavioral ecology and evolutionary genetics to clarify reproductive barrier dynamics, particularly in diverse and vulnerable taxa like frogs.

Adaptive patterns of anti-predator escape behavior in a globally introduced bird species

Grim T, Dor R, **Hauber M**

¹ASRC GC CUNY

POSTER SESSION 1 - **P01.160**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Introduced species can represent quasi-experimental, anthropogenic case studies of both ecological and evolutionary principles. When these species are firmly established, competitive interactions between native and introduced species interactions, including foraging, spacing, and breeding competition, may become costs of such species invasions. In turn, genetic and/or plasticity-driven changes in behavior and morphology could also take place in the invading species with increasing introduction lag (time since the onset of introduction). Critically, however, introduction lag is difficult to study in any single non-native population without long-term observations, and, instead, it requires geographically repeated measures of the focal response variables across invasive populations that were introduced at different times. Here we tested a priori predictors of predator-avoidance behaviors through the flight initiation distance (FID) assay of a widely distributed invasive bird species, the common myna *Acridotheres*

tristis. The species was extensively and consistently sampled throughout most of its independently introduced ranges across all hemispheres. Critically, FID increased with greater introduction lag. We also detected additional functional patterns in that FID increased towards the rural range within a continuous metric of urban-rural gradient and also at shorter distances from the Equator. Any robust study of FID must also include proximate predictors as well and, accordingly, we found that FID increased with greater starting distance, with lower immediate human density, with flighted over walking escape responses, and at lower heights of a bird's perch above ground but was unrelated to myna group size. Respectively, these factors are informative about the sensory cues triggering anti-predator behaviors in invasive mynas and imply an adaptive set of patterns of anti-predator responses in the introduced ranges of this species.

An empirical test of Baker's law: Dispersal favors increased rates of self-fertilization

Mccauley M^{1,2}, Milligan W^{2,3}, Lin J², Penley M², Quinn L⁴, Morran L²

¹Florida International University, ²Emory University, ³Columbia University, ⁴Washington University

POSTER SESSION 1 - P01.169, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Baker's law is the observation that recently dispersed populations are more likely to be self-fertilizing than populations at the range core. The explanatory hypothesis is that dispersal favors self-fertilization due to reproductive assurance. *Caenorhabditis elegans* nematodes reproduce via either self-fertilization or outcrossing and frequently disperse in small numbers to new bacterial food sources. While *C. elegans* males facilitate outcrossing, males and outcrossing are rare in natural *C. elegans* populations. Here, we use experimental evolution to test if frequent dispersal selects for the invasion of self-fertilization into predominantly outcrossing populations. *C. elegans* dispersal often occurs in the dauer alternative life stage. Therefore, we tested

the effects of dispersal on rates of self-fertilization in populations exposed to dauer-inducing conditions and populations maintained under standard lab conditions. Overall, we found that populations required to disperse to new food sources rapidly evolved substantially elevated rates of self-fertilization compared to populations that were not required to disperse in both dauer and non-dauer populations. Our results demonstrate that frequent dispersal can readily favor the evolution of increased selfing rates in *C. elegans* populations, regardless of life stage. These data provide a potential mechanism to explain the dearth of outcrossing in natural populations of *C. elegans*.

Behavioral isolation between two color morphs of the Mourning Wheatear (*Oenanthe lugens*)

Cohen R², Kiat Y^{2,3}, Levin E², **Dor R**¹

¹Department of Natural Sciences, The Open University Of Israel, ²School of Zoology, Faculty of Life Sciences, Tel Aviv University, ³Steinhardt Museum of Natural History, Tel Aviv University

POSTER SESSION 1 - P01.174, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Closely related populations may provide insight into the mechanisms of the early stages of the speciation process. In birds, prezygotic isolation plays a major role in reproductive divergence, usually through behavioral interactions. The Mourning Wheatear (*Oenanthe lugens*) is a territorial insectivore found in arid rocky habitats adjacent to the Saharo-Sindian desert belt. Within the geographical range of the nominate subspecies (*O. l. lugens*) there is a distinct population of a dark morph, restricted to the black lava deserts of northeast Jordan and southern Syria. This population presents a distinct black plumage yet does not show genetic divergence from the typical pale morph. This raises questions about the extent of reproductive isolation between the two morphs and the taxonomic status of the dark morph.

In this study we used behavioral experiments and genetic data in order to examine the reproductive isolation between these morphs. Behavioral assays using dummies tested whether pale-morph territorial

individuals respond differently to their own versus the dark morph. Genetic data was used for phylogenetic reconstruction and population differentiation analysis. Overall behavioral responses did not differ significantly between the morphs, however, pale-morph individuals showed a slightly stronger behavioral reaction to their own morph, suggesting a weak preference for familiar traits. Genetic analyses corroborate the lack of phylogenetic differentiation between the morphs, with 98% of genetic variation occurring within populations, indicating substantial gene flow. These findings suggest that the two morphs may represent populations in the early stages of divergence. While behavioral tendencies hint at emerging reproductive barriers, isolation remains incomplete, and ongoing hybridization is highly likely. Therefore, this study does not justify recognizing the dark morph as a distinct taxon. Further examination of phenotypic and genetic similarities and differences will enhance our understanding of the speciation process of these two morphs.

Common Origins, Divergent Paths: Gonadal Development in the Domestic Chicken and the Zebra Finch in the Context of Avian Evolution

Mizia P^{1,2}, Rams-Pociecha I^{1,2}, Piprek R¹, Rutkowska J³

¹Department of Comparative Anatomy, Institute of Zoology and Biomedical Research, Jagiellonian University, ²Doctoral School of Exact and Natural Sciences, Jagiellonian University, ³Institute of Environmental Sciences, Faculty of Biology, Jagiellonian University

POSTER SESSION 1 - P01.183, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The domestic chicken (*Gallus gallus domesticus*) and the zebra finch (*Taeniopygia guttata*) are representatives of different evolutionary lines. The phylogenetic lineages leading to domestic chicken (Galloanserae) and zebra finch (Neoaves) diverged in the Cretaceous 71 million years ago. Given the deep evolutionary split between Galloanserae and Neoaves, examining gonadal development in these two species allows us to identify which aspects of sex differentiation are conserved across birds, and which may have evolved uniquely within each lineage.

Eggs were collected on the day they were laid and incubated at 37.5 °C and 70% humidity. Embryos dissected from eggs were staged according to Hamburger-Hamilton tables, fixed in Bouin's solution and embedded in paraffin. We performed histological staining using Dubreuil's modification and to enhance our analysis, we used immunofluorescence with the use of antibodies against factors involved in sex determination.

Our results indicated that asymmetry in gonads is visible from the beginning their primordia formation. The left gonadal ridge is thicker than the right even before the PGCs (primordial germ cells) had settled. After PGCs had settled, we observed that in the zebra finch the left gonadal ridge exhibited a significantly higher number of PGCs than the

right, further enhancing the asymmetry. The ovarian development followed a comparable trajectory in both species, marked by the growth of the cortex and a reduction of the medulla. Notably, asymmetry was evident, as the left ovary had a more prominent cortex, while the right ovary remained underdeveloped. Testis differentiation followed a uniform pattern, involving cortical reduction and medullary expansion. Rapid growth of the right testis minimized asymmetry between both male gonads. Interestingly, in zebra finches, the left testis in some specimens showed disrupted structure, with a hermaphroditic appearance combining seminiferous tubules and ovarian-like cortex.

Our study demonstrates that while the domestic chicken and zebra finch share common early mechanisms of gonadal differentiation, species-specific differences emerge from the initial stages of development and persist following sexual differentiation. Despite their common use as model species in avian research, the chicken and zebra finch exhibit markedly different gonadal development trajectories. This highlights the importance of comparative studies for understanding both conserved and divergent aspects of reproductive development across bird lineages.

Consequences of range shifts on the genetic diversity of butterflies in Finland

Fernández Multigner L¹, Bras A¹, Saastamoinen M¹

¹University Of Helsinki

POSTER SESSION 1 - **P01.168**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Many species are shifting their range to track the most suitable environmental conditions in response to global warming. This strategy can improve the chances of species' long-term persistence. However, colonisation events, lower population densities, and strong selection pressures at the expanding range margin can result in reduced genetic diversity at the local populations. Lower habitat availability and connectivity in the range edge can also restrict the expansion, gene flow and population size, with further effects at the genetic level.

Although the loss of genetic diversity during range shift could be only temporary, a rapid and continuous increase in temperatures could cause range shifts to be too swift to allow for genetic diversity recovery. Selection pressures that might help marginal populations expand can also lose effectiveness if the genetic variability is too low for selection to act on. Such scenario will leave expanding edge populations in a particularly vulnerable position. Alternatively, if enough gene flow is maintained between the range edge and other populations, which can be enhanced by the landscape and habitat connectivity, the genetic diversity may be recovered. There is abundant theory on the interplay of

colonisation effects, selection and gene flow on the genetics of edge populations, and simulation studies showing a reduction in genetic diversity due to range expansion. However, few studies have looked at these patterns and the underlying processes in natural populations across different species.

To test these hypotheses, three range-shifting and two non-range-shifting butterfly species in Finland were chosen as model organisms. For each species, ten individuals from three populations in the expanding edge of the distribution range and three in the core of the distribution were sampled for full genome analyses. Each individual was sequenced with a low-coverage whole-genome resequencing approach and will be used to estimate population genetic diversity. We will also look for signs of selection affecting the populations of the range margin. We expect to observe lower genetic diversity in expanding populations than in core populations, and to find stronger differences in species that have expanded northwards over the last decades. Preliminary data from the genetic analyses will be presented here. In future, we aim to link the genetic diversity estimates to the habitat availability and connectivity within the real landscapes.

Dispersal evolution can only rescue a limited set of species from climate change

Kamal P¹, Thompson P², Lewis N^{1,3}, Fronhofer E¹

¹Institut des Sciences de l'Evolution Montpellier, ²Fisheries and Oceans Canada, Pacific Science Enterprise Centre, ³Department of Ecology & Evolution, University of Lausanne, Biophore

POSTER SESSION 1 - P01.161, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Anthropogenic climate change threatens biodiversity on Earth. In response, species can adapt evolutionarily to changing environments or shift their ranges via dispersal. However, dispersal itself can evolve on ecological timescales. We explore theoretically how dispersal evolution modulates the response of metacommunities to climate change. We find that this response depends on the environmental conditions prior to climate change. Variable environments harbour few, dispersive species that are likely to survive climate change by shifting their ranges with

their evolved dispersal abilities. Stable environments house many, less dispersive species. Their survival during climate change is less likely, as they can evolve robust, low dispersal traits that prevent range shifts. We identify a limited set of scenarios in which contemporary dispersal evolution can rescue species from climate change, highlighting the importance of species' evolutionary histories and evolutionary rates, as determined by their genotype-phenotype maps, for their responses to rapid environmental change.

Divergence at the edge: genomic signatures of adaptation in marginal populations of the European mole (*Talpa europaea*)

Colangelo P^{1,6}, Gentile G², Gramolini L¹, Ladurner E³, Kranebitter P³, Loy A⁴, Hutterer R⁵, Franchini P²

¹National Research Council, Research Institute on Terrestrial Ecosystems, ²Department of Ecological and Biological Sciences, University of Tuscia, ³Museum of Nature South Tyrol, Bolzano, Italy,

⁴Department Bioscience and Territory, University of Molise, ⁵Museum Koenig, Leibniz Institute for the Analysis of Biodiversity Change, ⁶NBFC - National Biodiversity Future Center

POSTER SESSION 1 - **P01.184**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Moles exhibit unique adaptations to a subterranean lifestyle, and their biology and distribution are highly constrained by soil characteristics. Most known species are restricted to relatively narrow regions in the Mediterranean peninsulas and the Middle East, suggesting that geographic isolation and Plio-Pleistocene climatic fluctuations have played a primary role in the speciation processes within the genus. In contrast, the European mole (*Talpa europaea*), unlike most other *Talpa* species, has an unusually wide distribution across Europe. At the southern edge of *T. europaea* range, genetically distinct populations exist in Italy, an area less suitable for the species, where interspecific competition with two other species well adapted to Mediterranean climatic conditions may occur. According to previous studies based on mitochondrial DNA (mtDNA), these Italian populations have been diverging for a long time and remained isolated within the Italian Peninsula even during interglacial phases. As such, the Italian populations represent a valuable system for studying the evolution of this subterranean mammal at the geographic and ecological margins of its range. These data can also provide novel insights into the speciation mechanisms that have shaped the entire genus.

Using a genome-wide SNP dataset, we investigated population structure, historical demography, and signals of local adaptation in *T. europaea*, with a particular focus on this marginal Italian population. Our results confirm the existence of two major genetic lineages, European and Italian, consistent with previous mtDNA analyses. Notably,

northeastern Italy harbors a highly diverse population belonging to the European lineage, possibly reflecting the occurrence of past secondary contact.

Within the Italian lineage, we detected strong genetic substructure, suggesting that environmental heterogeneity across the peninsula, along with potential interspecific competition with other *Talpa* species endemic to the region, has driven further diversification.

Demographic reconstructions revealed that the European lineage underwent post-glacial expansion, while the Italian lineage experienced earlier growth during colder Pleistocene phases. Despite evidence of demographic expansion and potential historical secondary contact, we found weak signs of gene flow between the two lineages, suggesting ongoing reproductive or ecological isolation. Genome-wide scans for selection identified lineage-specific fixed alleles under positive selection in the Italian lineage, particularly in genes associated with hypoxia response pathways, critical for survival in subterranean environments. These findings point to distinct adaptive pressures operating across the species range, especially at its ecological margins.

Overall, our study highlights how climatic history, population structure, isolation, and local adaptation interact to shape evolutionary trajectories at range margins. *T. europaea* serves as a unique model for exploring the genomic basis of divergence and adaptation in marginal populations, with broader implications for understanding evolutionary dynamics and speciation mechanisms in mole species.

Estimating individual stress along expansion ranges: a telomere based approach

Brahy G¹, Manicki A¹, Gueraud F¹, Ducos C¹, Minjou M¹, Oddou-Muratorio S¹, Labonne J¹

¹ECOBIO Inrae, University of Pau and Pays de l'Adour (UPPA)

POSTER SESSION 1 - P01.188, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Telomeres, repetitive sequences that protect chromosome extremities, are progressively eroded with aging processes in many taxa. This erosion accelerates under harsh environmental conditions. Consequently, relative telomere length (RTL) is commonly used in ecology as a proxy for physiological stress.

Population expanding in space usually experience contrasted environmental conditions from the core to the edge of their repartition range. Using RTL in this context can provide insight into the relative oxidative stress experienced by colonizing individuals. We investigate this hypothesis through the case of the Kerguelen Islands colonization by

brown trout (*Salmo trutta*), comparing RTL among individuals across different populations along the expansion range. The originality of our approach is that we sampled multiple locations and time points, with up to four temporal samples per location and multiple individuals per temporal sample. This sampling design enables us to disentangle the effects of population age, individual size, and sampling year on RTL, as well as their interactions.

Our aim is to identify a stress gradient along the expansion front and, ultimately, detect footprints of adaptation to the peculiar conditions generated by expanding metapopulations.

Evolutionary suicide in the secondary contact zone

Keaney T¹, Ramakrishnan A², Kokko H¹

¹Johannes Gutenberg-Universität Mainz, ²Indian Institute of Science Education and Research Pune

POSTER SESSION 1 - P01.186, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Rapid evolution can facilitate persistence in the face of environmental change, or increase the likelihood of coexistence between competing species via character displacement. However, adaptation does not always increase the likelihood of population persistence. In this talk, I will present theoretical extensions demonstrating that secondary contact between recently diverged populations can produce a rare case of evolutionary suicide. The logic behind this result is as follows. When males mate with both con- and heterospecific females, they can reduce population growth in heterospecific populations, through the production of inviable zygotes. However, this misdirected mating effort can have large negative effects on male fitness, producing strong selection

on males to discriminate between con- and heterospecific females. Thus, an evolutionary response is expected in both populations, resulting in less severe reproductive interference. However, if the two interacting populations show different evolvabilities for male discriminative ability, the degree to which males reproductively interfere with heterospecific females becomes asymmetric, with males from the slower evolving population having a larger relative effect on the fecundity of females in the other. If this difference in evolvability is sufficiently large, the species showing the more rapid response to selection can be driven to extinction. I will finish by discussing the generality of this result, and by outlining how this effect could be identified in nature.

From Breakthrough to Breakdown? Genetic Consequences of a Rapid Range Expansion in a Key European Pollinator.

Nash W^{1,2,3}, Haerty W^{2,3}, Knight M⁴

¹The Natural History Museum, ²The Earlham Institute, ³The University of East Anglia, ⁴The University of Plymouth

POSTER SESSION 1 - P01.189, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Rapid range expansions place populations under unique evolutionary pressures that shape their success in novel environments. Connectivity between forming subpopulations can maintain genetic diversity—but is this always preserved? Individuals at the expansion front often act as founders, but how much does their contribution define the genetic structure of resulting populations? We utilise the recent and ongoing range expansion of the Tree Bumblebee (*Bombus hypnorum*) to examine evolutionary dynamics at a species' range margin. First recorded in the UK in 2001, *B. hypnorum* rapidly colonised the UK and Ireland and is now one of the country's most abundant bumblebee pollinators. Using a population genomic dataset of 285 individuals spanning both the spatial (continental Europe, UK) and temporal (2002–2015) dimensions of the expansion,

we investigate origin, structure, and genome-wide divergence across the European population. In line with earlier findings, we show that the UK population was not shaped by a severe founding bottleneck, but we detect elevated inbreeding ten years after colonisation. We find no evidence of ongoing admixture with the continental population, and demographic reconstruction reveals a declining effective population size as the expansion progressed. Although overall divergence from the continental source remains low, we identify a set of divergent loci across the genome, suggesting some adaptive potential has been retained. Our findings demonstrate that range expansion and demographic success do not preclude the emergence of genetic vulnerability—particularly at the shifting frontiers of a species' distribution.

Genomic architecture of genetic differentiation in two hybridizing mussels from the mid-Atlantic Ridge

Diaz-Recio Lorenzo C^{1,2}, Thomas-Bulle C³, Le Port A¹, Daguin-Thiébaud C¹, Fuenzalida G⁴, Comtet T¹, Jollivet D¹

¹Station Biologique de Roscoff, ²Sorbonne University, ³Institute of Ecology and Evolution - Universität Bern, ⁴Instituto de Fomento Pesquero

POSTER SESSION 1 - P01.185, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The mussels *Bathymodiolus azoricus* and *B. puteoserpentis* serve as keystone, ecosystem engineers across the Mid-Atlantic Ridge, creating complex, rugose habitats that support substantial biodiversity at deep-sea hydrothermal vents. These environments, however, meet criteria for both Ecologically and Biologically Significant Areas (EBSAs) under the Convention on Biological Diversity and the FAO's Vulnerable Marine Ecosystems, necessitating protection from anthropogenic disturbances. Of particular concern is the mining of Seafloor Massive Sulphides (SMS), which threatens to disrupt vent plumbing systems and alter local conditions to which these species are specifically adapted, promoting local extinctions. This study, therefore, aimed to elucidate fine-scale patterns of gene flow between species and populations therein of *Bathymodiolus* mussels across 24 hydrothermal sites, spanning approximately 7,000 km of the Mid-Atlantic Ridge, and to determine whether genomic patterns reflect geographic isolation and local adaptation. We employed double-digest restriction site-associated DNA sequencing (ddRAD) to generate genomic libraries and used the *B. heckeriae* reference genome to identify single nucleotide polymorphisms (SNPs) with STACKSv2. Outlier loci were detected using multiple genome-scan approaches. Population genomic structure was assessed through principal component analysis (PCA) and ADMIXTURE, while demographic inference (ongoing) will be conducted using the ABC DILS method. Migration patterns were inferred using divMigrate and compared with larval dispersal models. Genotype-environment associations were investigated through distance-based redundancy analysis (db-RDA). As expected, the first axis of the PCA (PC1) and ADMIXTURE analysis clearly separated the two species with a few F2 and F3 or backcrosses at

the Broken Spur and Snake Pit vent sites. At the species level, outlier SNPs found by genome scan methods corresponded to species-diagnostic markers primarily responsible for variation along PC1. These were concentrated within several portions of chromosomes, indicating chromosome-specific genomic incompatibility between *B. azoricus* and *B. puteoserpentis* (islands of speciation). Outlier SNPs corresponding to PC2 and those highly correlated with environmental variables revealed subtle population structure in both species, pointing to potential temporal instability of introgression over a four-year period and the arrival of foreign alleles from unsampled stepping-stone vents. This temporal evolution of the mussel genetic structure is mainly due to the local extinction of some source populations associated with the vent instability. Functionally significant outlier SNPs were identified within genes involved in DNA repair mechanisms, adaptation to depth, and diurnal rhythms. Changes in allele frequency of outlier loci were highly correlated with latitude, volcanic composition, and sampling year. Our findings reveal a complex, mosaic hybrid zone that likely includes unsampled vents serving as stepping stones for gene flow. Understanding these fine-scale genomic processes provides critical insights into how *Bathymodiolus* populations may respond to anthropogenic disturbances at local scales. These results contribute essential data for evidence-based policy development and the designation of Regional Environmental Management Plans for these vulnerable deep-sea ecosystems. The hitherto unknown temporal instability observed over just four years highlights the dynamic nature of metapopulations where sink populations can become sources and vice versa, emphasising the need for ongoing monitoring and adaptive management approaches.

Genomic diversity of jaguars at the edge of their range

Pisciottano F¹, Campos M¹, Gabaldón T², **Saragüeta P**¹

¹Instituto de Biología y Medicina Experimental-CONICET, ²Barcelona Supercomputing Center (BSC), Institute for Research in Biomedicine (IRB), and Universitat Pompeu Fabra (UPF)

POSTER SESSION 1 - P01.190, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The jaguar (*Panthera onca*) population in Argentina decreased by more than 95% throughout the 20th century, restricting this species to an estimate of only 250 animals that live in small isolated groups in the northernmost regions of the country. This situation could imply that the last Argentine jaguar populations are undergoing a process of genomic erosion, which would represent a serious threat to their survival. However, a lack of genomic characterization of these animals prevents us from understanding the health status of these populations in terms of genetic diversity.

In this work we propose, to carry out a genomic characterization of this species from samples of Argentine individuals. For this purpose, we sequenced the complete genomes of 9 Argentinean jaguar samples at high depth (>20X). Additionally, we downloaded whole genome sequencing (WGS) data from 12 individuals from other border countries available in SRA. We used perSVade pipeline to process the short

sequencing reads for all these samples, performing quality checks and reads trimming, followed by the alignment of high quality reads to an improved chromosome-level assembly reference genome obtained from a local sample. The complete set of genome-wide variants was obtained through a joint calling approach using GATK tools. To characterize the variation of the generated data, we carried out genomic diversity analysis in order to obtain per-sample heterozygosity levels. We performed a sample clustering based on >11 million of genome-wide SNVs and applied STRUCTURE in search for signatures of population structure among the Argentine samples and in relation to the other American samples. The sustainability of subsisting jaguar populations in the southernmost limit of their current range requires knowledge about the state of genetic variability levels of extant individuals so as to avoid genetic erosion in these populations.

Genomic Effects of the Successful Post-Glacial Expansion of *Bombina pachypus*

Muñoz Mora V¹, Gargano M², Giannelli F², Fava S², Chiocchio A³, Giralda L⁴, Biello R¹, Iannucci A⁴, Canestrelli D³, Ciofi C⁴, Trucchi E², Bertorelle G¹

¹University of Ferrara, ²Marche Polytechnic University, ³University of Tuscia, ⁴University of Florence

POSTER SESSION 1 - P01.175, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The population expansion range can be a natural response to climate change. In fact, many populations have extended or changed their ranges after the Last Glacial Maximum period, successfully colonizing newly available habitats. The success or failure of such range expansions depends on several ecological and evolutionary factors such as dispersal limitations, changes in gene flow, founder effects, adaptive capacity to novel environments, and the accumulation of deleterious mutations during the expansion, a phenomenon known as expansion load.

Many studies have increasingly focused on expansion load as a limiting factor in the expansion of populations. It is known that allele frequencies change during a range expansion, which can rise in frequency and become fixed at the front of an expanding range due to genetic drift (allele surfing). While allele surfing can occasionally promote adaptive variants, it more commonly facilitates the spread of deleterious alleles, thereby contributing to the expansion load.

Understanding the consequences caused by these phenomena may help in efforts against invasive species or for designing effective conservation translocation programs. As global climate change forces more populations to shift their ranges to survive, these may experience reduced fitness due to expansion load and loss of genetic diversity. These genetic issues can increase extinction risks, especially when populations face stochastic or catastrophic events.

This work aims to analyse the dynamics of masked and realized components of the expansion load and their fitness effects in a case of successful post-glacial expansion. We used the Apennine yellow-bellied toad

(*Bombina pachypus*), an endangered endemic Italian species that expanded from a glacial refugium in Southern Italy northwards along the peninsula after the Last Glacial Maximum, as a model. To simulate this expansion, we used SLiM to develop forward-in-time genomic simulations applying a spatially continuous model. The simulated landscape was generated using past habitat suitability maps derived from ecological niche models, based on current and historical bioclimatic variables and occurrence records of *Bombina pachypus*. To enhance realism, we incorporated key life history traits of the species (dispersal ability, age at reproduction, lifespan), ecological features (competition, carrying capacity, habitat suitability), and genomic factors (accumulation of deleterious and neutral mutations in coding and non-coding simulated regions based on empirical data).

Our preliminary results suggest that the simulations can plausibly replicate the hypothesized colonization route of *B. pachypus* through the Italian peninsula. Moreover, we observe that edge populations accumulate more realized load than core populations, which tend to harbor more masked load, resulting in a greater fitness decline at the expanding front. However, in some simulation replicates, this expansion load does not prevent the population from continuing to colonize new areas.

We are currently conducting further analyses to understand how expansion load varies across different zones of the population (core, intermediate, and marginal areas), and how individual dispersal capacity and intraspecific competition affect the amount of expansion load, fitness reduction, and the overall success of the geographical expansion.

Gradients of increased reproductive effort and increased leakiness in sex expression with range expansion in the dioecious plant *Mercurialis annua*

Nguyen M¹, Pannell J¹

¹University Of Lausanne

POSTER SESSION 1 - **P01.164**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Population density influences both mating opportunities and resource competition in sessile plants. During a species range expansion, edge populations frequently experience low densities, imposing selective pressures on reproductive traits. Notions surrounding ‘Baker’s Law’ predict an increased capacity for uniparental reproduction such as self-fertilization in recently colonized populations in response to selection for reproductive assurance under low mate availability. Similarly, life-history theory predicts a shift toward enhanced reproductive effort in the low-competition environments of colonizing species. Here, we present clear evidence for both these effects in *Mercurialis annua*, a

dioecious wind-pollinated herb that expanded its range across Europe from the eastern Mediterranean Basin. In a common garden experiment using seeds sampled across the species’ natural range, we found a significant increase in the number of individuals with leaky sex expression toward the range margin. Reproductive effort (reproductive number divided by total biomass) also increased with expansion towards the species’ range margins. Our findings thus demonstrate evidence for evolution of both the sexual system and the life history together, consistent with Baker’s Law and increased investment towards reproduction during a range expansion.

Pan-range SNP phylogeography highlights differing effects of postglacial colonisation history on mitochondrial, autosomal, and sex-linked genome compartments

Sherlock M^{1,2,3}, Day J², Wilkinson M³, Jeffries D⁴

¹Institute of Vertebrate Biology, ²Genetics, Evolution and Environment, University College London,

³Natural History Museum, ⁴Institute of Ecology and Evolution, University of Bern

POSTER SESSION 1 - P01.172, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

During Pleistocene glaciations the Iberian Peninsula comprised multiple refugia, from which spatial genetic clusters and diversity hotspots developed. The routes and timing of recolonisation from such refugia have shaped the current distribution of genetic diversity in this region and throughout Europe. However, this process affects the various genome compartments (nuclear, mtDNA, sex chromosomes) differently. Characterising these differences can yield important insights into evolutionary processes that occur during recolonisation, as well as informing on general evolutionary dynamics of each compartment. In this study we sampled and sequenced (ddRADseq) 468 individuals of the cold-tolerant Iberian endemic amphibian, *Rana iberica*, from 51 sites across its entire species range. Using multiple phylogeographic analyses, including Approximate Bayesian Computation, we find that (1) the metapopulation of *R. iberica* is divided into

broad northern and southern groups corresponding to alternative colonisation routes from the core refugium; (2) genetic diversity is dominated by strong isolation-by-distance, indicating range expansion via stepping stone colonisation; (3) this stepping stone process had profound effects on sex-linked genetic diversity on the sex chromosomes, suggesting different male vs female dispersal tendencies and highlighting the sorely understudied effects of demographics on sex chromosome evolution; and (4) populations in and around the Sistema Central are highly distinct genetically, suggesting a period of consistent and prolonged isolation. These results contribute to our understanding of how cold-tolerant species respond to glacial cycles and the subsequent post-glacial warming that follows, and show how the demographic processes involved can have important and varying effects on different genome compartments.

Phylogeography of the shrimp *Palaemon longirostris* reveals high connectivity along the Atlantic European coast with a latitudinal gradient in diversity

Gonzalez Ortegon E¹, Lejeusne C², Naveira H³, Green A⁴, Martínez-Lage A³

³Departamento de Biología Celular y Molecular, CICA, Universidade da Coruña,, ⁴Department of Conservation Biology and Global Change, Estación Biológica de Doñana (EBD), CSIC

POSTER SESSION 1 - P01.187, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

This study aimed to investigate intraspecific genetic differentiation and geographic structure in the estuarine shrimp *Palaemon longirostris* along the Atlantic East Coast. The study encompassed 23 estuaries along the Atlantic East Coast. A total of 324 COI sequences were analyzed, including 314 newly generated sequences and 10 retrieved from GenBank. Haplotype networks (TCS), Bayesian skyline plots (BSPs), and AMOVA were employed to assess population structure and genetic differentiation. Rarefaction analyses addressed potential biases from unequal sample sizes across regions. Genetic diversity metrics, including haplotype and nucleotide diversity, were estimated, and patterns of isolation by distance were evaluated using Mantel tests. Analysis revealed a continuous gradient of haplotypes along the latitudinal axis of the

eastern Atlantic coasts, with a notable increase in private haplotypes in the southern region. Three distinct haplogroups were identified: one associated with North Atlantic waters bordering the Western Iberian Peninsula, the Alboran Sea, and North Africa; another comprising estuaries from the Bay of Biscay, the English Channel, and the North Sea; and a third formed by estuaries of the Irish Sea rivers. The Iberian Peninsula exhibited the highest haplotype diversity, aligning with rarefaction results that indicated saturation at higher sampling efforts. Genetic differentiation data indicate a recent population expansion subsequent to a bottleneck or founder event originating from southern populations, with the Gulf of Cadiz acting as both an ancestral zone and a source for estuaries along the Atlantic East Coast.

Populations on the Edge: Range Dynamics and Conservation of Great Crested Newts Under Global Change

Towler C¹, Lancaster L¹, Layton K^{1,4}, O'Brien D², Briers R³, Bocedi G¹

¹University Of Aberdeen, ²NatureScot, ³Edinburgh Napier University, ⁴University of Toronto Mississauga

POSTER SESSION 1 - P01.166, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Great crested newts (*Triturus cristatus*) have declined across their range from years of habitat degradation, fragmentation, and loss. They now face new challenges under climate change which could further exacerbate declines. Edge of range populations in the Scottish Highlands are genetically distinct and ecologically important due to the unique habitats they occupy (such as more acidic ponds with pH as low as 4.9) as well as the multitude of processes which may shape their range boundaries in future, including increased drought frequency from warming

temperatures and land-use changes. The aim of this project is to combine individual process-based modelling in RangeshiftR with population genomics methods from target sequence capture data collected across an environmental gradient in the UK and Europe. We will use this to investigate how the interaction of multiple stressors could affect the future persistence, adaptation and range expansion of *T. cristatus* and provide a scientific basis for conservation management strategies in Scotland.

Reconstructing the Evolutionary History of the Genus *Orestias* (Teleostei: Cyprinodontidae): An Integrative Phylogenomic, Morphological, and Biogeographic Approach across the Central Andes

Acevedo A^{1,2}, Araya V¹, Barrera S³, Sarmiento J³, Rodríguez J⁴, Moreno E⁵, Hinojosa F¹, **Mendez M**¹

¹University of Chile, ²Instituto de Ciencias Naturales - UNAL, ³Museo Nacional de Historia Natural,

⁴Museo de Biodiversidad del Perú, ⁵Universidad Nacional del Altiplano

POSTER SESSION 1 - P01.181, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The genus *Orestias* (Cyprinodontidae) comprises a diverse radiation of freshwater fishes endemic to high-altitude aquatic ecosystems in the Central Andes, particularly the Titicaca-Desaguadero-Poopó-Salares (TDPS) system and adjacent basins across Peru, Bolivia, and Chile. These fishes inhabit dynamic landscapes shaped by paleolake cycles (e.g., Mataro, Minchin, Tauca), altitudinal gradients, and repeated episodes of hydrological isolation, which are hypothesized to have driven speciation through geographic fragmentation. To explore diversification patterns across the genus, we integrated mitochondrial markers (Cyt b, D-loop), genome-wide SNPs, and 54 morphometric traits. Morphological measurements were obtained from 1250 individuals representing 33 species, including type material and specimens housed in major biological collections. Additionally, extensive field sampling was conducted across more than 85 localities covering the known distribution of the genus. Phylogenetic analyses based on molecular data revealed multiple well-supported clades that correspond to historically proposed complexes such as *agassii*, *cuvieri*, and *gilsoni*. However, contrary to earlier taxonomic classifications, we did not recover the *mulleri* group as a cohesive

clade, suggesting its artificial nature. Hierarchical clustering of morphometric data reinforced these molecular groupings and validated species boundaries by grouping holotypes and syntypes within their respective clusters. Biogeographically, our results support Lake Titicaca as a major center of diversification, particularly for the *cuvieri* and *gilsoni* complexes, while the more widely distributed *agassii* complex emerged as polyphyletic, reflecting historical isolation across fragmented Andean basins. The concordance between morphological, genomic, and spatial data highlights the role of past hydrological connections and disconnections in promoting cryptic speciation and adaptive radiation. This integrative study advances our understanding of evolutionary processes in *Orestias*, refining the systematics of the group and emphasizing the importance of landscape history in shaping vertebrate diversity in one of South America's most vulnerable high-altitude ecosystems.

Funding: This work was supported by the Agencia Nacional de Investigación y Desarrollo de Chile (ANID) [grant ANID FONDECYT 1250559; 1221214, 3240022 and CHIC ANID FB210018].

Revisiting Classic Theories to Explain Global Patterns of Genetic Diversity

Garcia A¹, Stapley J², Nobis M¹, Csilléry K¹

¹Swiss Federal Research Institute WSL, ²ETH Zurich

POSTER SESSION 1 - P01.179, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Genetic diversity is nature's toolkit for survival, the reservoir of genetic variation that fuels evolution, drives adaptation and builds resilience. It underpins species' long-term survival, making it a key metric for conservation, offering insights into vulnerability and adaptive potential. As global change accelerates, understanding what shapes this diversity has never been more urgent. Mapping global patterns of genetic diversity offers critical insight into the link between microevolutionary processes and macroevolutionary patterns, ultimately helping forecast responses to global change for the identification and optimization of conservation priorities.

Over the past decades, several theories have proposed broad-scale expectations for how genetic diversity is distributed across space. The Central-Marginal Hypothesis (CMH) predicts declining diversity toward the edges of a species' range; the Latitudinal Diversity Gradient in Genetic Diversity (LDG) suggests a decrease in diversity with increasing latitude; and the Refugia Hypothesis (RH) posits that genetic patterns today reflect legacies of isolation in glacial refugia. Though frequently cited and explored in local studies, these theories remain largely untested at global scales with standardized population-level data.

Here, we present GenDivRange, a curated dataset compiling genetic diversity metrics

from the growing body of population-level genomic studies across taxa and regions, and use it to reexamine these foundational hypotheses through a macrogenetic framework. By harmonizing genetic diversity metrics from 1,480 studies, we systematically test the support for these foundational hypotheses across taxa and geographic scales.

Our results show consistent support for the CMH and RH across most taxonomic groups, while LDG-GD patterns appear more taxon- and life-history-specific, reflecting greater context dependency. These findings are in agreement with predictions of long-standing population genetic theory but also highlight the importance of scale and history in shaping genetic diversity. Our framework moves macrogenetics from data mining toward theory-driven synthesis and offers a scalable framework for identifying geographic and taxonomic priorities in large-scale conservation planning, shifting the emphasis from isolated case studies to broad taxonomic patterns. This shift is poised to significantly improve the long-term effectiveness and cost-efficiency of conservation strategies in the face of changing climate. The GenDivRange project welcomes the submission of both new and existing data, fostering data sharing and promoting its application in conservation efforts.

Sex ratio in core, edge and refuge populations of *Mercurialis annua*: Home and away

Sapir Y¹, Bar-Lev Y¹, Amer N¹, Morim E¹, Lyu S², Pannell J², Pannell J³

¹Tel Aviv University, ²University of Lausanne, ³<https://ecorama.github.io/>

POSTER SESSION 1 - **P01.176**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The sex ratios of dioecious plants are expected to approximate 1:1 when parental investment is equal across sexes. However, biased ratios frequently occur, either as primary bias through reduced female or male seed production, or via differential germination and mortality patterns. Under environmental stress, female plants typically underperform compared to males due to higher reproductive costs, resulting in male-biased ratios. Nevertheless, plant adaptation may include sex-specific responses to stressors, potentially maintaining balanced sex ratios in locally adapted populations. Conversely, genetic constraints such as sex chromosomes and wind pollination mechanisms have been associated with female-biased ratios, regardless of the environment.

As part of ECORAMA project, we examined adaptation in the dioecious annual plant *Mercurialis annua* L. across its core range (central Europe), range edge (North-Western Europe), and a glaciation refuge (Middle East). Seeds from these three regions were cultivated for one generation under controlled conditions to eliminate maternal effects, before being planted in 10 experimental plots throughout Europe and the Middle East.

We hypothesized that sex ratio would remain equal across regions, while growing away from home inducing male-biased ratios through environmental stress. Specifically, we predicted that refuge populations would show 1:1 sex ratio in both home and away, due to higher genetic diversity, while edge populations would demonstrate male-biased ratios when grown in core and refuge sites due to environmental stress.

We found that sex ratio did not deviate from 1:1 in core and edge populations in their home region. No significant deviations from 1:1 sex ratio were observed in any origin - experimental site combination, except refuge populations in their home region, which displayed a significant male bias. Additionally, female proportions in refuge populations were slightly higher than core or edge populations across all experimental sites.

We conclude that sex ratio in *M. annua* remains largely unaffected by environmental perturbations. As a wind-pollinated annual with sex chromosomes, *M. annua* maintains consistent sex ratios across environments. Geographical range expansion does not alter sex ratios, suggesting that sex ratio cannot serve as an indicator of adaptation.

Speciation between populations at the margins of *Solanum chilense*: Phenotypic differences and transcriptomics of maternal effects in F1 hybrids.

Muntaha S¹, Tellier A¹, Silva-Arias G²

¹Technical University of Munich, ²Instituto de Ciencias Naturales, Universidad Nacional de Colombia

POSTER SESSION 1 - **P01.173**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Wild tomatoes (*Solanum* section *Lycopersicon*) are a good model system for studying plant demography and local adaptation to abiotic stresses. Adaptation to the local environment is a primary force driving morphological evolution and allopatric speciation. *Solanum chilense* is considered one of the most promising genetic resource for tomato breeding to biotic and abiotic stresses. From northern Chile, *S. chilense* extended its range by colonizing southwards two arid habitats around the Atacama Desert: 1) along the coast ca. 150,000 years ago, and 2) in the highlands of the Andes ca. 30,000 years ago. These marginal populations evolve in allopatry and show footprints of local adaptation, driving divergence at the genetic and phenotypic levels. This system thus constitutes a model of speciation in action between isolated populations at the margins of the species range. We want to investigate the genetic bases of the observed reproductive isolation between these marginal most southern populations (coastal and highland) of *S. chilense*.

First, we document phenotypic and genetic differences between populations. We compare the effect of drought under controlled climatic conditions across

populations of *Solanum chilense*. We use seven parental accessions —LA4107, LA3111, LA1963, LA4330, LA4117A, LA2932, LA2755—from different local habitats. We measure seed germination rate, plant growth parameters, physiological responses, and morphological traits. Our results reveal wide variability within and between accessions, indicating the polygenic and multi-trait nature of drought tolerance and local adaptation in *Solanum chilense*.

We successfully produced both F1 and F2 generations based on various crosses between coastal and highland populations and indeed observed strong incompatibility. We notably observed a pronounced maternal effect in the crosses between coastal and highland populations LA4107× LA4117A. To further validate and decipher the genetic bases of this maternal incompatibility effect, we are conducting an RNA-Seq experiment focusing on early root and stem developmental stages. Our results reveal differentially expressed genes likely responsible for developmental differences between the reciprocal crosses, and we use genomic data to assess whether these genes also exhibit signatures of local adaptation, such as selective sweeps.

The Evolutionary Path and Divergence of the *Oncocyclus* Irises Species Complex Across the Southern Levant

Bar-Lev Y¹, Lozada-Gobilard S², Xavier A³, Glick L¹, Mayrose I¹, Sapir Y¹

¹Tel Aviv University, ²Lund University, ³Indian Institute of Science, Education and Research

POSTER SESSION 1 - **P01.178**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Understanding the mechanisms by which populations evolve and diverge into distinct species is a central question in evolutionary biology. Speciation is a continuous process, with species often existing at various stages of divergence. Despite extensive research on speciation, it was rarely studied in species in the course of speciation, which can offer valuable insights into divergence evolution.

Materials and Methods: This study focuses on eight Israeli *Oncocyclus* Iris species, commonly known as the Royal Irises, which are thought to be in an ongoing speciation process. These species are either endemic or sub-endemic to Israel, with populations that are highly fragmented and distributed across a range of ecological habitats. Our goal was to explore the roles of geographic isolation and ecological differentiation in the divergence process of this evolutionary-young group. We employed restriction-site associated DNA sequencing (RADseq) to reconstruct the phylogeographic history and

to decipher the spatial and ecological evolutionary relationships among populations.

Results: Our phylogenetic analyses were largely consistent with current taxonomic classifications. *Iris bismarckiana* consistently emerged as genetically distinct from all other species. In most analyses, *I. atropurpurea* and *I. mariae* also formed a separate clade. However, several species traditionally defined by morphological traits and distribution could not be genetically differentiated. We found significant correlations between genetic relatedness and both geographic proximity and ecological variables.

Conclusions: These findings indicate that both geographic separation and adaptation to local environmental conditions contribute to genetic divergence within the Royal Irises. This supports the hypothesis that they represent a species complex in the early stages of speciation.

The genotype-phenotype map of repeated seasonal adaptation during range expansion of a butterfly

Gotthard K¹, Shoshan A¹

¹Department of Zoology, Stockholm University

POSTER SESSION 1 - **P01.180**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The relationship between genotype and phenotype is a central aspect of evolutionary biology. It determines how phenotypic selection affects genetic variation which may lead to adaptation in natural populations. Examples of repeated phenotypic adaptation in response to similar selection (through parallel or convergent evolution) raises the question if it is typically due to parallel genetic changes? I.e. is the repeated evolution of the same trait value due to selection among allelic variants of the same genes, so called gene reuse, or are there alternative genomic routes leading to the same phenotypic adaptation?

The evolution of photoperiodism for life cycle regulation in insects have led to repeated, and remarkably predictable, adaptive clines across latitudes. The shared selection pressures, due to highly predictable changes in daylengths across latitude and strong selection on the annual number of generations (voltinism), are relatively well understood. However, to what extent this repeated adaptation is due to genetic parallelism and gene reuse is still unknown. We have explored this question by assessing the consistency of the genotype-phenotype map during repeated evolution of photoperiodism for induction of winter dormancy (diapause) in the northern range margin of the Speckled wood butterfly (*Pararge aegeria*). In common garden experiments we demonstrate adaptive variation in the critical daylength for diapause induction (CDL) among latitudinally distinct Swedish populations, while a phylogeographic analysis of whole-

genome sequences suggests that similar CDL:s have evolved repeatedly during at least three independent colonizations of new and still isolated areas (large Baltic islands). A QTL analysis using crosses between two distant populations and a GWAS of nine Swedish populations converged on both Z-linked and autosomal genes in the circadian clock being associated with adaptive variation in CDL. However, independent crosses between several different populations suggest that while Z-linked genetic variation is associated with CDL evolution among populations at the Swedish mainland, it has not been involved in the evolution of CDL on the isolated Baltic island of Gotland. Instead, we show that this island population appears to be fixed for a large deletion in the autosomal clock gene, *timeless*, that when introgressed into a mainland population recovers a large proportion of the Gotland CDL phenotype. Hence, we conclude that the evolution of CDL in the Gotland population appears largely to be due to a structural mutation that does not exist in any of the other populations with a similar CDL. In combination these results suggest that the genotype-phenotype map for repeated adaptation of CDL in *P. aegeria* varies across the species range margin. However, we still find a recurrent pattern of allelic variation at circadian clock genes, including *timeless*, being associated with the evolution of photoperiodism across populations, suggesting a strong element of gene reuse during repeated seasonal adaptation in the northern range margin of *P. aegeria*.

The K-tabase: A Comprehensive Database of Plant Genetic Diversity and Population Structure Statistics for Macrogenetic Analysis.

Adenegha T¹, Lancaster L¹, Herrera-Alsina L¹, Lustenhouwer N¹

¹University Of Aberdeen

POSTER SESSION 1 - P01.170, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Macrogenetics, the study of large-scale patterns and predictors of intraspecific genetic variation across species, can play a significant role in our understanding of evolution and biodiversity. The number of genetic clusters (K) is a commonly reported metric of genetic structure, that provides information about how genetic populations are distributed within and across geographic regions. However, there has been little empirical effort to synthesize the information in 'K' across studies to address global questions, such as how latitude, phytogeographic boundaries, and distance from past refugia influence the degree of genetic diversity and structure within plant taxa. Utilising published datasets, I am curating the "K-tabase", a database containing population structure and genetic diversity metrics for over 2000 plant taxa from across the globe. With the large

taxonomic representation and spatial coverage, I will evaluate how impacts of phylogeny, life history, biogeography, and environments shape global patterns of population structure. I will further test how methodological factors such as spatial scale, sample sizes, genetic marker types, and estimation method impact inference and comparability of spatial genetic structure estimates across studies. The K-tabase will enable mapping of global variation in population structure, identify hotspots and breakpoints where genetic structure patterns overlap across many species, and develop insight on how these hotspots compare to other global partitioning of biogeographic zones and boundaries, providing a useful resource integrating macro-and micro-evolutionary processes for biogeography, conservation, and policy.

Uncovering Hybridization and Species Boundaries in Peripheral Populations of the Great Tit (*Parus major*) Using High-Resolution Genomics

Javaheri Tehrani S¹, Chen Y¹, Alaei Kakhki N², Vellnow N¹, Aliabadian M³, Gossmann T¹

¹Computational Systems Biology, Faculty of Biochemical and Chemical Engineering, TU Dortmund University, Dortmund, Germany, ²Computational Systems Biology, Faculty of Biochemical and Chemical Engineering, TU Dortmund University, Dortmund, Germany, ³Department of Zoology, State Museum of Natural History Stuttgart, Stuttgart, Germany, ⁴Computational Systems Biology, Faculty of Biochemical and Chemical Engineering, TU Dortmund University, Dortmund, Germany, ⁵Department of Biology, Faculty of Science, Ferdowsi University of Mashhad, Mashhad, Iran, ⁶Computational Systems Biology, Faculty of Biochemical and Chemical Engineering, TU Dortmund University, Dortmund, Germany

POSTER SESSION 1 - P01.171, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Hybrid zones at range margins offer unique opportunities to investigate how genetic novelties emerge and persist over evolutionary timescales. Peripheral populations often experience distinct selective pressures and increased genetic drift, facilitating the formation of novel genetic combinations through hybridization—combinations that may drive local adaptation or even the origin of new taxa. In the *Parus major* species complex, which includes four phylogenetic lineages across Eurasia (*bokharensis*, *cinereous*, *minor*, and *major*), secondary contact has occurred since the Pleistocene, resulting in several zones of hybridization. We focus on a proposed three-species contact zone in northeastern Iran involving *bokharensis*, *cinereous*, and *major*, with particular attention to the hypothesized hybrid origin of *Parus major intermedius*. Using high-resolution genomic data, we find evidence of recent introgression between *intermedius* and *bokharensis*; however, *P. m. intermedius* does not conform to the

classical definition of a hybrid species. Instead, it displays unique genetic signatures that point to a complex demographic history. Mitochondrial haplotype networks and phylogenetic tree analyses reveal that *P. m. intermedius* is genetically distinct from central European populations. Moreover, its low mitochondrial diversity and high genetic differentiation suggest that it represents a peripheral population. We also detect ongoing gene flow within the contact zone: *bokharensis* individuals exhibit introgression from *major*, while European *major* populations retain signatures of ongoing introgression from *intermedius*. These introgressed genotypes contribute to the genetic diversity of the *Parus major* complex and may serve as a reservoir for adaptive potential. Our findings shed light on the intricate dynamics of hybridization and introgression, offering valuable insights into speciation and the genetic architecture of species boundaries shaped by both ancient and ongoing evolutionary processes.

Unraveling the evolutionary history of *Orestias agassii*: a phylogeographic study considering its current range.

POSTER SESSION 1 - P01.163, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The Altiplano system serves as a natural laboratory for studying diversification due to its complex geological and paleoclimatic history. The genus *Orestias* comprises 46 endemic species found in the Altiplano and high-altitude inter-Andean systems in Peru, Bolivia, and Chile. Previous research has mainly focused on morphological analyses; however, unclear species boundaries and inconsistent taxonomic practices have complicated species identification. *Orestias agassii* is the most widely distributed species in this genus, occurring across various hydrographic basins in Chile, Bolivia, and Peru. Consequently, individuals identified as *O. agassii* may actually belong to several different species.

In this study, we conducted a systematic and phylogeographic analysis across the entire distribution range of *O. agassii*. We sampled 65 localities and collected a total of 710 individual specimens. We amplified the mitochondrial markers control region D-loop and Cytochrome b and performed phylogenetic reconstructions using both Bayesian Inference and Maximum Likelihood methods. We assessed genetic diversity through various indices and haplotype networks. Patterns of population structuring were examined using the SAMOVA and Geneland programs. Additionally, we conducted species delimitation using Cytb sequences employing three different methods: ABGD, mPTP, and ASAP.

Genetic structuring analyses revealed a clear pattern of differentiation between the Amazon basin in the Cusco region and the other basins included in our study. This distinction was evident in both haplotypic networks and the topology of the phylogenetic trees. Moreover, all other basins formed a cohesive unit. Phylogenetic analyses and haplotype networks suggested that this pattern is closely related to the hydrography of the Altiplano. Additionally, species delimitation analyses identified five candidate species. These findings are consistent with the phylogenetic and genetic structuring results, which indicate that the Cusco localities are distinctly separate from all others. Meanwhile, the Titicaca, Desaguadero, Beni, Pampa del Tamarugal, Uyuni, and Altiplano basins collectively form a single group.

We conclude that the current distribution of *O. agassii* does not correspond to a single species. Instead, we propose the following candidate species/ lineages: the first comprises the populations from Chile, Bolivia, and Peru (excluding Cusco), which corresponds to *O. agassii*; the second includes three distinct species or lineage for the Amazon basin, incorporating the Cusco localities.

POSTER SESSION 1 - P01.162, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Understanding species' range size and why closely related species can have drastically different distributions is a fundamental question in biology. This has implications in ecology, evolutionary biology, biogeography, and species conservation. However, answering this question is challenging due to the multiple inter-related factors that shape species distributions, particularly in continental regions, where unclear ecological and geographic boundaries and long evolutionary histories obscure the main drivers of range size variation.

Island-like ecosystems such as caves, oceanic islands, and mountain tops provide exceptional models for studying species' biogeography and evolution due to their well-defined boundaries and relatively simplified ecosystems. Despite their advantages for research, subterranean habitats remain poorly studied compared to surface ecosystems, largely due to accessibility challenges—a phenomenon often referred to as the Racovitzan impediment. Paradoxically, these habitats, which offer key insights into evolutionary and ecological processes, are also highly vulnerable to human-induced impacts, putting species living there at risk of extinction even before we can fully understand their evolutionary history.

In this study, we aim to better understand the factors influencing distributional range size in cave and subterranean species, using European spiders as a model system.

Materials and Methods: We compiled the most up-to-date database of European cave and subterranean spider distributions to analyze the factors shaping their range sizes. We used Variation Partitioning Analysis to determine the relative influence of phenotypic cave adaptations, historical factors, and potential sampling biases on various range size metrics.

Results: Our results indicate that the most significant determinant of range size in subterranean spiders is the degree of phenotypic adaptation to a subterranean lifestyle, particularly eye reduction and, secondarily, loss of pigmentation, whereas limb elongation had no significant effect. In contrast, historical factors, such as past temperature fluctuations and ice coverage during the Last Glacial Maximum, played a lesser role. Sampling biases had minimal impact on range sizes, but other unaccounted factors and taxonomic relationships also appeared to influence species distributional range.

Conclusions: Adaptation to highly selective subterranean environments leads to specialized traits, with eye loss being one of the most distinctive. Our findings suggest that this trait is also linked to a reduction in species' range size among European subterranean spiders. Those findings will help future evolutionary and conservation studies focused in these often poorly understood ecosystems.

Adaptation to 44 years of climate change across a gradient from niche center to edge

Van Deurs S¹, Fior S¹, Luqman H^{1,3}, Reutimann O¹, Mayzlish Gati E², Singer A², Lifshitz D², **Alexander J**¹

¹ETH Zürich, ²Israel Gene Bank, ³University of Cambridge

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Background: Evolution is expected to contribute to the persistence of populations exposed to changing climate, especially at range margins along the warm edge of a species' distribution. However, demonstrations of rapid evolution in wild populations associated with climate change are extremely scarce. Instead, inferences about possible adaptive responses often rely on "space-for-time" approaches, which have assumptions that can be difficult to verify. Resurrection experiments offer a direct method to observe evolutionary changes over time, but these rarely span the periods of several decades over which climatic shifts have occurred. In this study, we combine space-for-time inferences, based on genomic and phenotypic data, with resurrection experiments to investigate the evolution of the annual plant *Lactuca serriola* following 44 years of climate change near its arid range edge in Israel. We ask (1) do populations show signs of adaptation to climate along a gradient from niche center to niche edge? (2) Have populations evolved to changing climate? (3) What are the implications of this for evolution at range margins?

Materials and methods: In 2020 we sampled 21 populations of *L. serriola* across Israel, spanning a steep precipitation gradient from the mesic north to the arid south, where the species reaches its arid range and niche edge. We first used low-coverage whole genome sequencing (n=329) and environmental association analyses to test for genomic signatures of adaptation across this gradient from niche center to edge. Next, seeds from 2020 populations were paired with collections made from the same 21 locations in 1976. Plants from these pairings were grown in a common garden in a greenhouse in Zürich, Switzerland, for two generations, and monitored for phenological transitions. We focused on phenology as it is known from previous work to be involved in climate

adaptation in this species, with advanced flowering associated with populations from warmer and drier climates. We used mixed effects models to test the hypothesis that flowering time is earlier in populations from more arid climates (space-for-time prediction) and in the 2020 vs 1976 cohorts (climate change prediction).

Results: We identified 108 candidate genes with significant associations with Israel's gradient in precipitation of the wettest month. Partial allelic turnover for the majority of these genes (67%) was strongest towards the niche edge. Enrichment analyses revealed selection acted on genes associated with phenology and abiotic stress responses at the niche edge, and biotic interactions (e.g. defense) closer to the niche center. In the common garden experiment, we found that flowering time in the second greenhouse generation was over 6 days earlier in contemporary (2020 cohort) than ancestral plants (1976 cohort). However, contrary to our hypothesis, plants originating from drier populations flowered later than those from wetter populations, and there was no significant interaction between the precipitation gradient and cohort.

Conclusions: Our findings provide direct evidence for rapid adaptation to climate change in a wild species, even at its arid range edge. Hindcasting of the adaptive genetic composition of our populations based on the environmental associations observed in 2020 also suggest that adaptation has occurred at the range edge in the last 44 years. What the limits to this adaptation are, however, remain to be determined. Furthermore, the mismatch between space-for-time predictions and observed evolutionary shifts in phenology over time caution about inferring evolutionary responses to climate change from spatial adaptive variation observed today.

Digestive efficiency and mitochondrial phenotype underlie the rapid evolution of a faster pace-of-life at the margins of a range-expanding species

Jorissen S¹, Pichaud N², Van Belleghem S¹, Swaegers J¹, Stoks R¹

¹KU Leuven, ²Université de Moncton

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Due to global change, many species are shifting their distribution and encounter new thermal conditions. Evidence is mounting that this may not only cause plastic trait changes, but also rapid evolution of traits and of their thermal plasticity. These traits do not react and evolve to the environment in isolation but they form a correlated set of life-history, physiological and behavioural traits that make up a pace-of-life (POL). The POL concept states that life-history, behavioural and physiological traits covary together as the result of energy trade-offs in allocating resources toward growth, survival and reproduction and thereby align along a fast to slow continuum. Despite that the POL concept has proven to be a powerful predictive framework, to explain patterns of trait macro-evolution among species, much less is known whether it also can predict trait evolution among the populations at the range margins. In addition, an emerging hypothesis suggests that, apart from the food digestive metabolism, the mitochondrial phenotype (efficiency and density) contributes to POL variations across the thermal regimes at the range margins. To deepen this understanding, we investigated the thermal evolution and plasticity of the POL and its underlying mechanisms by making use of the southward range expansion of the damselfly *Ischnura elegans*, from France into warmer regions of Spain. Warmer temperatures generally result in a faster POL. However, unfavourable habitats at the range margins, due to founder effects and low densities, may instead result in a slower POL. This contrast makes

studying a southward range expansion particularly intriguing. Alongside the ancestral French region, we studied two Spanish regions: a 'new edge' region founded 10 years ago (Salamanca) and an 'old edge' region founded 70 years ago (Murcia-Alicante). In a common garden experiment, larvae and adults from all regions were exposed to French and Spanish summer temperatures. Our results confirmed that the old edge region evolved a faster POL than the ancestral region when exposed to Spanish temperatures. As hypothesized, the old edge individuals had higher mitochondrial and digestive efficiencies supporting their evolved fast POL. Additionally, the larvae and adults showed higher mitochondrial densities, further sustaining this pace. In contrast, the new edge region showed maladaptive traits, exhibiting a slower POL than the ancestral region when exposed to Spanish temperatures. Such maladaptive responses may reflect that populations at the new range margin indeed occupy less favourable habitats with lower densities compared to the ancestral region. In addition, these individuals increased their food intake, likely prioritizing energy allocation toward repair mechanisms to cope with thermal stress. In conclusion, our findings highlight that the traditional POL framework, which links food intake to fast POL traits, may require refinement as we show for the first time that the mitochondrial phenotype can be an important driver of rapid evolution of the POL at the range margins.

Eco-evolutionary feedback of thermal adaptation during range expansion

Naik S^{1,2}, Fronhofer E¹

¹ISEM, ²IISER

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Temperature fundamentally drives biological processes across scales—from protein kinetics to species distributions. While molecular studies focus on protein stability and enzyme function, and ecological studies often emphasize emergent traits like fitness or range shifts, these perspectives are rarely integrated. This disconnect limits our understanding of how protein-level thermal adaptation scales up to influence ecological and evolutionary patterns.

We bridge this gap by integrating two mechanistic models of temperature-dependent biological rates into an eco-evolutionary range expansion framework. First, we consider the Protein denaturation based model (Chen et al. 2019), which links organismal growth to the fraction of functional proteins and has been supported by studies across viruses, bacteria, and insects. Second, we apply the Macromolecular rate theory (Hobbs et al. 2013), grounded in transition state theory, which attributes thermal performance curve (TPC) curvature to enthalpic and entropic

changes in enzyme reactions—especially relevant in cold-adapted species.

By embedding these models within a spatially explicit, evolving population model, we investigate how thermodynamic constraints affect birth, death, and density dependence, and thus shape range expansion dynamics. Using simulations, we compare how each model influences expansion speeds, asymmetry in TPCs, and emergent trait distributions across landscapes.

Our results show that mechanistic assumptions at the molecular level critically affect macroecological outcomes. Specifically, different sensitivities to mutations under each model lead to distinct thermal trait evolution patterns, range limits, and biodiversity maintenance mechanisms. We highlight the utility of mutation sensitivity maps in linking molecular adaptation to eco-evolutionary dynamics, emphasizing that a pluralistic, thermodynamically-informed framework is essential for predicting biological responses to global temperature change.

Flowering responses of the woodland strawberry to local climate and reduced precipitation along a European latitudinal gradient

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Climate change creates novel environmental conditions that plant species must adapt to. Since plants are finely tuned to the seasonality of their environments, shifts in the timing of their phenological activities serve as some of the most compelling evidence of climate change's impact. Thus, understanding how key phenological traits linked to fitness, such as the onset of flowering, respond to novel environments is crucial for assessing the plastic and/or adaptive potential of species to persist in the face of climate change. In this study, we investigated the onset of flowering in *Fragaria vesca* (woodland strawberry; Rosaceae) by translocating genotypes between four sites along a south-north gradient in Europe, encompassing its entire latitudinal distribution range with varying temperatures, precipitation patterns, and photoperiods. At each site, we included a reduced precipitation treatment using rain-out shelters to simulate drought conditions and assess their impact on flowering onset. Our findings revealed that southern and central European genotypes exhibited a delayed

onset of flowering when translocated to the northernmost site. In contrast, no difference among genotypes was found in the onset of flowering when grown in more southerly sites. Additionally, reduced precipitation accelerated flowering across several sites and all genotypes, irrespective of their latitudinal origin. Overall, our results revealed that northern European genotypes showed a greater capacity to adjust their onset of flowering in response to the different photoperiods and temperatures across the latitudinal gradient compared to southern European genotypes, suggesting that they may be more resilient to shifting environmental conditions. Furthermore, the differential response of phenotypic plasticity across genotypes, when translocated at higher versus lower latitudes, highlights the role of photoperiod when assessing a species' ability to cope with climate change.

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

When genotypes show reduced fitness due to the phenotypes they produce in novel environments, genetic variation in plasticity could aide population persistence by reducing the severity of predicted fitness declines. However, we know little about the potential for standing genetic variation in plasticity to determine population persistence beyond current range margins. At four elevations on Mt Etna, we transplanted 40 clones per elevation for each of 19 genotypes of a Sicilian daisy, *Senecio chrysanthemifolius*, and estimated their plasticity and fitness within and native and novel elevations. We show that different

directions and magnitudes of plasticity are favoured across elevations, and that genetic variation in plasticity has different effects on fitness in novel and native environments, as well as within versus among elevations. Different genotypes also show surprisingly different patterns of gene expression variation that affect fitness in response to these native and novel environments. In particular, we show that genetic variation in plasticity that is typically hidden within the native range becomes visible in novel environments, and may be crucial for allowing population persistence when faced with rapid environmental change.

Sexual selection shapes eco-evolutionary dynamics at range margins

Bocedi G¹

¹University Of Aberdeen

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Understanding what processes shape the dynamics of species' geographic range limits is one ongoing central question in ecology and evolution. One potentially key process is sexual selection; yet theory examining how sexual selection could affect eco-evolutionary dynamics in marginal populations is still lacking. In species with separate sexes, range limits could be shaped by limitations in encountering mates at low densities. Sexual selection could therefore modulate mate limitation and thereby extinction-colonisation dynamics at range margins, through evolution of mate encounter ability and/or mate competition traits, and their demographic consequences. Further, as sexual selection has been hypothesised to reduce genetic load, it may play a role in preventing the accumulation of expansion load during species' range expansion and thereby prevent reduction in

fitness at the leading front populations. I will present results from two theoretical models. The first model demonstrates that evolution of species' ranges may be importantly shaped by feedbacks between sexual selection and spatial population demography and dynamics. The second model shows that sexual selection, in interaction with dispersal evolution, may have a considerable, sometimes counterintuitive, role in reducing accumulation of expansion load in front populations. Together, these results underscore the potential role of sexual selection in shaping eco-evolutionary dynamics at range margins, highlighting the need for further theoretical and empirical exploration in this relatively understudied area.

The causes of elevational range limits: insights from population genomic and quantitative genetic approaches

Narasimhan A¹, Flury J^{1,2}, di Santo L¹, Felber J¹, Bachmann O¹, Riedl S¹, Willi Y¹

¹University Of Basel, ²University of Oulu

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Background: Why species are restricted within spatial boundaries is a central question in ecology and evolutionary biology, and it has been studied for over 200 years. With no general answers, the search for the causes of range limits is ongoing. Several possible causes may contribute to range limits, including (but not limited to) depletion of genetic diversity due to small population sizes and genetic drift, and low genetic variances for key adaptive traits. Further, an understudied but potentially important cause may be the genetic non-independence of traits, which can constrain adaptation beyond boundaries. Here, we conducted a comprehensive evaluation of why the evolutionary niche of species is often conserved. We tested this hypothesis on elevational gradients, where environmental change occurs over short geographic distances.

Methods: For the first part, we collected seeds of three high- and three low-elevation Brassicaceae species in the core and both the lower and upper range edges, from two separate mountain transects in different regions of Switzerland. We estimated population-level inbreeding coefficients and genetic differentiation among populations using whole-genome sequencing data. For the second, we chose one transect per species and raised offspring plants of matrilineal lines in the greenhouse under two thermal treatments: warm and control. We measured key growth and leaf traits that diverge across elevation in Brassicaceae and estimated the genetic covariance (G-)matrix for each population and the two growth treatments.

Results: Based on the population genomic approach, we found that populations from elevational range edges did not have reduced genomic diversity nor were they more inbred relative to populations from the core. However, all populations on a transect were genetically differentiated, sometimes to small but always to significant extents. Based on the quantitative genetic approach, we found that G-matrices were relatively stable between treatments and among populations of high-elevation species, though we detected strong differentiation among populations for the low-elevation species. Multivariate genetic variances were lower in high- as compared to low-elevation species, potentially threatening the high-elevation species with lower adaptive potential. When constraining effects of genetic covariances were considered, evolvabilities diminished proportionally for all species and populations, indicating the general role of genetic constraints in reducing the adaptive potential.

Conclusions: Overall, our combined population genomic and quantitative genetic approach yielded deep insights into the causes of elevational ranges in Brassicaceae. First, our results do not support the hypothesis that reduced effective population size is involved – directly or indirectly – in the context of elevational ranges. Second, our findings indicate that the genetic architecture constrains the evolutionary response and contributes to maintaining species' elevational range limits.

The impact of climate change on the adaptive potential of alpine plants

Nomoto H¹, Alexander J¹, Fior S¹

¹ETH Zurich

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

A species' adaptive potential is crucial for determining its chances of persistence when facing climate change. Previous studies have suggested that plants can evolve in response to climate change, yet little is known about how alterations in selection regimes under climate change can act to alter adaptive potential. Here, we use a transplant experiment along an elevation gradient, simulating climate warming and changing competitive interactions, to investigate the potential role of selection imposed under climate change in shaping the adaptive potential of three alpine plant species. First, we empirically estimated directional, stabilizing, disruptive and correlational selection acting on leaf morphology under scenarios of gradual warming and changing competitive interactions. Second, we inferred how

changes in selection regimes due to climate warming and changing competitive interactions acted to alter the adaptive potential through their effects on simulated G-matrices. Warming caused shifts from disruptive to non-significant and stabilizing selection for *Plantago alpina* and *Anthyllis vulneraria* ssp. *alpestris*, respectively, which acted to reduce adaptive potential. When *P. alpina* interacted with low instead of high-elevation species, selection shifted from non-significant to stabilizing, further contributing to reducing adaptive potential. Our study highlights that apart from selection imposed by climate warming, altered selection regimes under changing competitive interactions play crucial roles in shaping responses in alpine plants facing climate change, by eroding their adaptive potential.

Winters restrict a climate change-driven butterfly range expansion despite rapid evolution of seasonal timing traits at the range margin

Nielsen M^{1,2,3}, Ittonen M^{1,4}, Siemers I¹, Friberg M⁵, Gotthard K¹

¹Stockholm University, ²University of Bremen, ³University of Helsinki, ⁴University of Tartu, ⁵Lund University

MEETING ROOM 129+130, August 18, 2025, 2:00 PM - 5:00 PM

Background: Climate change pushes species toward higher latitudes and altitudes, but the proximate drivers of range expansions vary, and it is unclear whether evolution at range margins facilitates climate change-induced range changes. Over the past 20 years, wall brown butterflies (*Lasiommata megera*) have rapidly expanded northward in Sweden in association with climate change, providing the opportunity to test for a role of range margin evolution in this range expansion. A previous, lab-based common garden study identified evolution of winter diapause cues in range margin populations, but what effect does this have under natural conditions and does this trait actually limit the range?

Materials and Methods: We conducted a reciprocal transplant experiment, raising larvae descended from range interior and range margin populations of *L. megera* at sites 1) in the range interior, 2) at the northern range margin, and 3) beyond the current range margin. At the beginning of winter, we measured traits related to seasonal timing (diapause induction and growth rate), and after winter we checked their overwinter survival. With this experiment we both tested for local adaptation in these traits and evaluated to what extent local adaptation influences the on-going, climate-driven range expansion.

Results: Almost all individuals from all populations entered diapause at an appropriate time, despite the previously identified among-population variation in diapause induction thresholds. Caterpillars of northern descent, however, grew faster than those from southern populations, at all field sites. This may be a counter-gradient adaptation to compensate for the short, northern growing seasons, but we found no evidence for pre-winter body mass affecting winter survival. In fact, winter survival was low overall—extremely so at the beyond range site—regardless of population origin, indicating that the primary constraint to range expansion is an inability to adapt to winter conditions.

Conclusions: Although range-expanding *L. megera* show clear local evolution of two traits related to seasonal timing, these putative local adaptations likely do not contribute to range expansion, which is instead limited by winter survival. Thus, despite clear evidence for evolution of multiple traits at an expanding range margin, it is instead the unevolving traits that appear to set the range margin. To predict future range changes, it will therefore be important to distinguish between the traits that evolve during range expansion and those that set the range margin.

Diversity of sex chromosome gene regulation in squamate reptiles

Voukali E¹, Psenicka T¹, Kratochvil L¹, **Rovatsos M**¹

¹Faculty Of Science, Charles University

POSTER SESSION 2 - P02.053, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Differentiation of sex chromosomes is typically accompanied by the cessation of recombination and subsequent gene loss from the degenerated sex chromosome (Y or W), resulting in gene dosage imbalances between the sexes. Classical theory, based largely on studies in model organisms, predicts the evolution of mechanisms to compensate for these imbalances. Dosage compensation - or at least dosage balance in the expression of sex-linked genes - has been well documented in lineages with male heterogamety (XX/XY). In contrast, lineages with female heterogamety (ZZ/ZW) are often

thought to lack global, chromosome-wide regulatory mechanisms for gene dosage, particularly at the transcriptional level. In this study, we combined high-throughput sequencing with comparative bioinformatics to investigate patterns of transcriptional gene dose regulation in nine independently evolved sex chromosome systems of squamate reptiles. Our findings provide novel evidence from non-traditional model organisms, revealing the molecular diversity and evolutionary complexity of gene dose regulatory mechanisms across vertebrates.

Breeding system influences mating-type proteins evolution in *Microbotryum* fungi

Namias A¹, Snirc A¹, Rougemont Q¹, Rodriguez de la Vega R¹, Lucotte E¹, Hood M², Giraud T¹

¹Université Paris-Saclay, CNRS, AgroParisTech, Ecologie Société Evolution, ²Department of Biology, Amherst College

POSTER SESSION 2 - P02.032, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

In numerous eukaryotic lineages, proteins involved in sexual compatibility are known to evolve faster than other proteins. In fungi, sexual compatibility is controlled by mating-type loci (MAT). In most basidiomycetes, there are two such loci: the P/R locus, encoding pheromone precursors and pheromone receptors, and the HD locus, encoding two homeodomain transcription factors, HD1 and HD2. In heterothallic fungi, mating can only occur between sporidia bearing distinct alleles at both of these loci. In some species, the great number of alleles at both loci results in a huge number of mating types. In most basidiomycetes, HD and P/R loci are found on distinct chromosomes, and the P/R loci is biallelic, showing an ancient trans-specific polymorphism. The HD locus shows distinct patterns depending on the species studied, being sometimes biallelic, most of the times multiallelic, and showing no wide-scale trans-specific polymorphism.

Microbotryum species, a.k.a. anther-smut fungi, infect and castrate a wide range of Caryophyllaceae species, and they are highly

selfing. The *Microbotryum* genus displays repeated independent events of linkage between HD and P/R loci. This results in two distinct breeding systems, either bifactorial, with unlinked HD and P/R loci, or unifactorial, with linked HD and P/R loci, which co-segregate. We studied the evolution of the HD genes, using the genomes of more than 30 *Microbotryum* species, with divergence times ranging from 0.4 to 11 million years. We show a strong influence of the breeding system on HD gene diversity and evolution: HD loci is multiallelic in bifactorial species, but biallelic in unifactorial species. We show that distinct parts of the HD genes show distinct evolutionary histories. Little trans-specific polymorphism is found outside of the HD1-HD2 interaction region, while this region, which acts as a single unit, shows an ancient trans-specific polymorphism. Most importantly, we show repeated independent events of HD loss of function in unifactorial species, with gene decays and even gene losses.

Disentangling the complex evolutionary history of sex chromosomes in snakes

Pšenička T¹, Augstenová B¹, Frynta D², Kornilios P³, Kratochvíl L¹, Rovatsos M¹

¹Department of Ecology, Faculty of Science, Charles University, ²Department of Zoology, Faculty of Science, Charles University, ³Department of Biology, University of Patras

POSTER SESSION 2 - **P02.038**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

For a long time, snakes were presented as a textbook example of a group with gradual differentiation of homologous ZZ/ZW sex chromosomes. However, recent advances revealed that the ZZ/ZW sex chromosomes characterize only caenophidian snakes and certain species of boas and pythons have nonhomologous XX/XY sex chromosomes. We used genome coverage analysis in four non-caenophidian species to identify their sex chromosomes, and we examined the homology of sex chromosomes across phylogenetically informative snake lineages. We identified sex chromosomes, both XX/XY and ZZ/ZW, for the first time in 13 species of non-caenophidian snakes, providing much deeper insights into the evolutionary history of snake sex chromosomes. The evolution of sex chromosomes in snakes is more

complex than previously thought. In non-caenophidian snakes, it must have involved sex chromosome turnovers and changes in heterogamety, resulting in bigger overall variability of mostly poorly differentiated sex chromosome systems. In contrast, sex chromosomes of caenophidian snakes attained remarkable evolutionary stability once their differentiation proceeded. Moreover, snake lineages must differ in rates of sex chromosome differentiation as homologous sex chromosome systems of similar age but strikingly different differentiation levels were demonstrated. Lastly, certain genomic regions were likely co-opted as sex chromosomes in several snake lineages independently. All of these points make snakes an excellent vertebrate model group to study general aspects of sex chromosome evolution in the future.

DNA methylation patterns underlying paternal genome silencing in the mealybug *Planococcus citri*

Woodman T¹, Marshall H², Ross L¹

¹University Of Edinburgh, ²University of Leicester

POSTER SESSION 2 - **P02.043**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Many organisms display sexually dimorphic traits regulated by differential expression and gene splicing. In the case of the mealybug *Planococcus citri*, sexual dimorphism is especially pronounced. Males and females differ dramatically in morphology, lifespan and the way they inherit genetic material. This is mediated by extreme sex-biased gene expression, despite mealybugs having no sex-specific genes, owing to a lack of sex chromosomes. This means that males and females are genetically identical, and therefore their differences are likely to be epigenetically regulated.

Mealybugs reproduce through paternal genome elimination (PGE), a form of genomic imprinting in which the haploid paternal genome in males is silenced in somatic cells and discarded from the germline, resulting in almost exclusively maternal expression and inheritance. The molecular mechanisms behind this paternal genome silencing are still under speculation, however previous research indicates DNA methylation may be involved. Mealybugs show distinct sex-specific DNA methylation profiles and considering the known involvement of DNA methylation in imprinting in mammals and plants, it is possible that it also plays a role in this species. Furthermore, mealybugs have independently evolved promoter methylation associated with gene silencing, a pattern more similar to mammals than to other insects. To further understand the role of DNA methylation in paternal genome silencing, we have combined RNA-seq and DNA methylation data along with parental single nucleotide polymorphism information to ascertain whether differential methylation occurs on the maternal or paternal chromosomes, and how this is linked to sex-biased gene expression as well as the differential behaviour of paternal chromosomes in males and females. Together these results will give insights into epigenetic regulation of sexual dimorphism and genomic imprinting in an insect with unique biology.

Elucidating molecular mechanisms of sex determination in stick insects

Gaudichau E¹, Djordjevic J, Schwander T¹

¹Unil

POSTER SESSION 2 - **P02.045**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sex determination is a key process in animal development, triggering the differentiation of primary and secondary sexual traits essential for reproduction. In animals, sex determination is controlled by highly conserved genes from the doublesex and mab-3 related transcription factor (DMRT) family. The gene doublesex was first discovered in the fly *Drosophila melanogaster*, followed by mab-3 in the worm *Caenorhabditis elegans* and finally the gene DMRT1 in vertebrates. DMRT genes underwent various duplication events and independently evolved sex determination functions in multiple animal taxa. In insects, sex determination is controlled by a cascade of genes that evolved around two genes called transformer and the DMRT family gene doublesex. Detailed molecular studies of these two genes in holometabolous insects suggested that insect sex determination is generally controlled via sex specific splicing. However, recent studies of a wider range of

insect species challenge this assumption. Here we investigated the evolution and sex-specific splicing and expression patterns of the genes doublesex and transformer in stick insects, a hemimetabolous insect order. Surprisingly, we found a duplication of the gene doublesex with both copies featuring similar expression patterns between the sexes and across tissues, and no evidence for sex specific splicing. A RNAi knockdown experiment targeting one of the two copies did not reveal any effect on male or female secondary sexual traits. By contrast, we found clear evidence for sex-specific splicing of the gene transformer. In combination with new findings in other hemimetabolous insect orders, our data show that sex determination mechanisms in these orders differ strikingly from those in holometabolous insects. Thereupon, the study of non-model insect species will be key for reconstructing the evolution of insect sex determination mechanisms.

Escape from a conserved system: Sex chromosome turnover in the Hispaniolan giant galliwasp (*Caribicus warreni*, Diploglossidae)

Augstenová B¹, Pšenička T², Langner C³, Kratochvíl L², **Rovatsos M**²

¹Biology Department, Vrije Universiteit Brussel, ²Faculty Of Science, Charles University, ³Allwetterzoo Münster

POSTER SESSION 2 - **P02.054**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Anguimorphan reptiles possess one of the oldest known sex chromosome systems among amniotes, likely originating in their common ancestor during the Early Cretaceous. These ZZ/ZW sex chromosomes are conserved across monitor lizards (Varanidae), beaded lizards (Helodermatidae), and the alligator lizard *Abronia lythrochila* (Anguidae). However, recent studies suggest that the anguimorphan family Shinisauridae and a part of the family Anguidae do not share this ancestral system, likely due to independent sex chromosome turnovers. To investigate the evolution of sex chromosomes within this group, we analyzed the gene content of cytogenetically identified ZZ/ZW microchromosomes in the Hispaniolan giant galliwasp (*Caribicus warreni*,

Diploglossidae) using comparative genome coverage analyses. Unexpectedly, the sex chromosomes of *C. warreni* are not syntenic with the ancestral anguimorphan system. Further genome coverage comparisons with species from the genera *Varanus* and *Heloderma*, along with qPCR-based gene dose assays of Z-linked genes, confirmed the absence of homology between the ancestral and derived diploglossid sex chromosomes. These findings indicate that, despite long-term stability in some anguimorphan lineages, sex chromosome turnover has occurred in others, making anguimorph reptiles a rare example of both deep conservation and occasional replacement of sex chromosome systems over tens of millions of years.

Evolution of Translation GTPases: From LUCA to Extant Diversity

Fer E^{1,2}, Kaçar B¹

¹Department of Bacteriology, University of Wisconsin-Madison, ²Microbiology Doctoral Training Program, University of Wisconsin-Madison

POSTER SESSION 2 - **P02.030**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Translation is a fundamental biological process that decodes genetic information encoded in mRNA to synthesize proteins. Having emerged around 4 billion years ago, translation is one of the most conserved cellular components. In this study, we investigate the evolutionary history and diversity of bacterial translation factors - particularly translation GTPases - using comparative analyses with their archaeal and eukaryotic homologs. Showing striking homology among translation GTPases, we suggest a common ancestral origin, likely predating LUCA and show that the elongation and initiation functions can be traced back to an ancient generalist form of translation GTPases. Our comparative

sequence and structure analysis reveal that the universal translation GTPases possess extension segments, particularly at their N- and C-terminal regions. Although the functional roles of these extensions remain unclear, our findings suggest that translation GTPases have undergone lineage-specific adaptations in response to diverse environmental pressures, contributing to the divergence of translation systems among the three domains of life. By identifying novel molecular features across time, our work provides new insights into the evolutionary mechanisms that have shaped the translation machinery from early life to the present.

Faster-X evolution in globular springtails

Ebdon S¹, Ross L², Jaron K¹

¹Wellcome Sanger Institute, ²University of Edinburgh

POSTER SESSION 2 - **P02.034**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The faster-X effect predicts that X chromosomes may evolve more rapidly than autosomes due to selection on expressed recessive alleles. Quantifying the effect empirically usually requires numerous assumptions due to the 'typical' biology of expression and inheritance, and so its strength remains unclear. Springtails present a novel opportunity to ameliorate this. Male globular springtails have hemizygous X chromosomes, diploid autosomes, and eliminate their paternal genome during spermatogenesis. This results in all chromosomes alternating between sexes and showing transmission bias between generations. Hence, the X chromosomes and autosomes only differ in

the fixation probability of male-beneficial alleles. We generated whole-genome resequencing and RNAseq data for the globular springtail *Allacma fusca*, to quantify the faster-X effect. We find that non-synonymous X-linked diversity is depleted relative to the autosomes. We infer the distribution of deleterious fitness effects (DFE) and find that new mutations on the X chromosomes show stronger fitness effects, indicative of greater purifying selection. Finally, accounting for the DFE, we see higher rates of adaptive evolution on the X chromosomes, supporting the faster-X effect.

From Genome to Function: Evidence of Transcriptional activity in Sciaridae Germline-Restricted Chromosomes

Kyriacou R¹, Herbet M¹, Ross L¹, Hodson C²

¹Institute Of Ecology And Evolution, University Of Edinburgh, ²University College London, UCL Department of Genetics, Evolution & Environment

POSTER SESSION 2 - **P02.044**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Various organisms eliminate large portions of their genome from somatic cells during early development; in extreme cases, entire chromosomes become restricted to the germline. These germline restricted chromosomes (GRCs) have evolved independently across the tree of life in diverse taxa, including hagfish, lamprey, passerine birds and three dipteran families: Cecidomyiidae (gall midges), Chironomidae (non-biting midges), and Sciaridae (fungus gnats). Recently, foundational genomic work has begun to unveil some of the mysteries behind GRC evolution in Sciaridae. Analysis in *Bradysia coprophila* has revealed that its two distinct GRCs are extremely gene-rich (~15,000 genes). Strikingly, whilst some of these genes are paralogs derived from somatic Sciarid core-chromosomes, many others appear phylogenetically distinct, with analysis placing them within the Cecidomyiid clade. Hence, Sciarid GRCs are presumed to have evolved from a hybridisation event between these two taxa. Whilst functional genomics in songbirds and lampreys has shown GRCs do express genes, often involved in germline cell development, differentiation and sex determination, no such work has been done on the Sciarid GRCs. Therefore, it remains an open and crucial question as to whether these large, and extremely gene rich chromosomes actively transcribe mRNA and produce functional proteins.

Here we address this question by combining genomic, transcriptomic and cytogenetic approaches to investigate whether transcription occurs from GRCs throughout various stages of *B. coprophila* development. We employ bulk RNA-seq on *B. coprophila* germline libraries (testes and

ovaries) in order to identify RNA reads mapping to GRC-linked scaffolds. Somatic libraries, which lack GRC RNA, served as controls to flag misaligned reads from highly similar core-chromosome paralogues. We stress that detecting GRC-gene expression using bulk RNA-seq is challenging. Reproductive tissue dissected from an individual contains a mix of somatic cells (containing only core-chromosomes) and germline cells (containing both GRCs and core chromosomes). Consequently, GRC transcripts are considerably underrepresented compared to those from core-chromosome. As a result, our approach likely detects only the most highly expressed GRC-linked genes.

We identify ~85 GRC-linked genes expressed throughout *B. coprophila* development, although this number falls to ~20 confidently expressed GRC-linked genes when accounting for core-chromosome read contamination. Of these confident GRC-linked genes, approximately half are expressed at the larval stages of development. We investigate the function of GRC genes using bioinformatic analyses and complement these findings with cytogenetic approaches to confirm gene expression and visualise the transcriptional activity of the GRC across developmental stages. The detection of only ~20 expressed genes out of over 15,000 annotated GRC-linked genes raises important questions about whether GRC transcription is truly limited to a small subset of genes, or whether more sensitive approaches—potentially targeting additional life stages or single-cell resolution—are needed to fully reveal their functional landscape.

Hermaphroditism in Insects; The Unbelievable Case of *Icerya purchasi*

Skarlou E¹, Ross L¹

¹University of Edinburgh

POSTER SESSION 2 - **P02.029**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Insects are one of the most diverse and widespread animal clades, harbouring almost all known mechanisms of sex determination. However, in stark contrast to its prevalence among many invertebrate groups, hermaphroditism in insects is virtually non-existent... except for a remarkable instance! The case of *Icerya purchasi*, a hemipteran plant parasite, commonly known as the cotton cushion scale insect.

I. purchasi is the only insect unequivocally described as androdioecious (i.e., its populations consist of male and hermaphrodite individuals) while also being a haplodiploid (i.e., males originate from unfertilized eggs). In this species, males are rare, making up just 0.01% to 10% of the population. The rest of the population is made up of hermaphrodite individuals, which despite looking like females, can produce both eggs and sperm at the same time. With self-fertilization as the dominant mode of reproduction, one can't help but wonder:

How can an otherwise fully female-looking and behaving individual produce sperm?

An enigma for the last 100 years, two main hypotheses have been competing to explain this biological puzzle. The prevailing

hypothesis posits that sperm in hermaphrodites originate from an established phenomenon called "polyspermy", in which multiple sperm enter an egg but only one fertilises it. The other sperm pronuclei persist and eventually form the sperm producing tissue in the adult hermaphrodite. Alternatively, the other hypothesis suggests that genome elimination in specific germline cells, during the hermaphrodite's development, produces the haploid sperm-producing tissue.

To unravel this mystery, we combined cytogenetic techniques with whole-genome computational analysis. Specifically, we used genomic staining methods such as DAPI and FISH to distinguish between the two proposed cytogenetic mechanisms. Then, to assess the paternal genetic contribution to the sperm tissue, we analyse genetic data from mother-offspring pairs.

These findings will elucidate the reproduction mechanisms of the only known androdioecious insect. Thus, paving the path for future population genetic inquiries into wild populations and allowing us to better understand the evolution of androdioecy, specifically in the context of insect haplodiploidy.

Insights into inheritance and genomic variation patterns following hybridisation between two divergent cichlid lineages

Saha J¹, Peona V^{2,3}, Svoldal H^{1,4}

¹University Of Antwerp, ²Evolutionary Biology Centre, Uppsala University, ³Swiss Ornithological Institute,

⁴Naturalis Biodiversity Center

POSTER SESSION 2 - P02.047, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Hybridisation plays a major role in speciation and formation of adaptive radiations by reshuffling genetic material. There can be a wide range of evolutionary consequences of such hybridisation events. It can give rise to species with novel adaptive traits and improved fitness compared to the parental lineages or it might also lead to accumulation of deleterious mutations that reduce the fitness of the hybrid species. Hybrid swarms are known to have played a key role in the rapid diversification of the East African cichlid radiations. Yet, how genomes from distantly related lineages interact to produce such variation remains only partially understood.

In this study we investigate a novel hybrid species that was produced by crossing two eco morphologically similar species but from distantly related lineages: *Maylandia emmiltos* from Lake Malawi and *Neochromis omnicaeruleus* from Lake Victoria. Both of these parental species are rock dwelling algae scrapers. Using long-read sequencing, we generated phased genome assemblies of hybrid individuals to reconstruct haploid parental genomes in the absence of reference genomes. Additionally we have also used short read sequencing for a large

number of the offsprings to study the effect of parental contributions in them.

Our analysis shows the variations segregating across the chromosomes in the hybrids is not always completely heterozygous. But in certain regions of the genome we observe an over representation of one parental lineage. This suggests asymmetric genomic contributions and potential selection acting on specific loci. Furthermore, we explored the occurrence of transposable elements (TEs) and their propagation across generations. Preliminary results indicate that there is a substantial amount of putative de novo transpositions that accumulate and require to be examined in more detail.

These findings highlight how hybridisation between divergent lineages not only combines distinct genetic backgrounds but also affects genome-level dynamics such as biased parental genome retention and TE proliferation. Our study aims to contribute towards a deeper understanding of how interactions between divergent genomes shape evolutionary outcomes in hybrid species.

IT'S A MATCH: using modelling to understand the evolution of fungal mating and incompatibility systems

van der Heijden S¹, **Lu D**¹

¹University Of Oslo

POSTER SESSION 2 - **P02.051**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Compatibility between fungal hyphae is governed by two contrasting systems depending on the life stage: During mating fungal hyphae seeks to fuse with genetically different hyphae and avoid selfing. On the other end, there are hyphae in the vegetative stage who only will allow fusion with itself and should reject non-self. Mating in fungi is governed by MAT-genes, increasing either the number MAT-loci or alleles at a given MAT-locus will increase the number of mating types which promotes outcrossing and increases the chance of mate compatibility. In the mushroom forming fungi a massive diversification in the number of alleles per MAT locus has taken place, but the number of MAT loci has not increased

beyond two. For vegetative compatibility, the opposite is the case. Here we find an increased number of incompatibility loci, but there are few alleles per loci. The current study attempts to use modelling and simulations to understand why we see a diversification in alleles but not in the number of loci for mating, and why the situation is reversed for vegetative compatibility. In the models, an increase in the number of alleles seemed to increase compatibility while promoting outcrossing, while an increase in the number of loci decreased compatibility and promoted outcrossing. In addition, we explore the effects that population size and population structure could have on these systems.

Massive genome expansion and rearrangement in an androdioecious scale insect

Galbraith J¹, Skarlou E¹, Peters N¹, Mongue A², Ross L¹

¹Institute of Ecology and Evolution, The University Of Edinburgh, ²Department of Entomology and Nematology, The University of Florida

POSTER SESSION 2 - P02.042, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The androdioecious mating system of the cottony cushion scale (*Icerya purchasi*) and other Iceryini are unique among insects, with populations consisting largely of selfing hermaphrodites, with rare haploid males allowing for occasional outcrossing. Selfing dramatically lowers effective population size, increasing both genetic drift and homozygosity across the genome, allowing novel variants to rapidly become homozygous. Due to the increased effect of drift, switches to selfing also initially allow transposable elements (TEs) to proliferate, in turn increasing genome size. However, on longer time scales genome size and TE load is observed to decrease in selfing and androdioecious species.

Compared to dioecious scale insects, the *Icerya purchasi* genome is 2 – 4 times larger, while its diploid chromosome count is smaller at 4, compared to the 6 – 34 chromosomes present in dioecious scale insects. To examine if androdioecy could have played a role in the expansion in *Icerya purchasi* genome size or affected genome structure we performed a comparative analysis of all scale insects sequenced to a chromosomal level. We found TE proliferation was responsible for much of

the increase in *Icerya* genome size. However, we observed a similar increase in TE load and genome size in an outcrossing species from the same family (Monophlebidae), suggesting this increase in genome size may have begun before the switch in mating system.

Within most families we found the chromosomal synteny of scale insects to be reasonably well conserved. In contrast, we found an abundance of large intrachromosomal rearrangements in *Icerya purchasi* since its divergence from dioecious species. Previous studies have found increased genome reshuffling in other Hemiptera with a reproductive mode which dramatically decreases outcrossing (parthenogenesis). This increase in chromosomal shuffling observed in *Icerya* may in part be due to the increased load of highly similar TEs, well known catalysts of chromosomal rearrangements through ectopic recombination. Additionally, selfing allows for massive chromosomal rearrangements to become homozygous within two generations, thereby reducing any negative fitness consequences of being heterozygous. Our results suggest androdioecy may have played a role in the massive genomic reshuffling present in the *Icerya* genome.

Mechanisms of transition to parthenogenesis in hybrid stick insects

Massy M¹, S. Blanc C¹, Schwander T¹

¹Université De Lausanne

POSTER SESSION 2 - **P02.039**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sexual reproduction is the most widespread mode of reproduction in multicellular organisms. But despite the prevalence of sex, many lineages have successfully evolved alternative reproductive strategies. Yet, the underlying mechanisms associated with transitions to alternative reproduction remain poorly understood, despite their various genomic and evolutionary consequences. For instance, certain non-sexual reproductive modes preserve heterozygosity, whereas others do not. As recessive load is expected to be associated with fertility costs, this can impact the success and persistence of non-sexual lineages. The elucidation of the cellular mechanisms that govern non-sexual reproduction consequently enhances our comprehension of their evolution. *Bacillus* stick insects are a unique genus characterized by a diverse array of reproductive strategies, including parthenogenesis, where females generate fertile eggs in the absence of fertilization, and hybridogenesis, where the maternal genome is clonally transmitted to fertilized eggs. Our

research team reconstructed the phylogenetic history of the genus, showing multiple transitions between various reproductive modes and ploidy levels. To understand the cellular mechanisms underlying these transitions, we characterized a *Bacillus* lineage that reflects an intermediate state in these transitions. This lineage is diploid, parthenogenetic, and a hybrid. By cytological reconstruction of the progression of meiosis, we demonstrated that the genome is duplicated before meiosis ("premeiotic replication"). This enables copies of identical chromosomes to pair instead of homologs from a different parental species. In those hybrids, recombination can therefore occur without loss of heterozygosity. Additionally, this mechanism enables transitions to triploidy and the generation of new parthenogenetic lineages. These results shed light on how transitions to asexual reproduction can occur in insects and more broadly strengthen the evidence that premeiotic replication is a common mechanism of parthenogenesis in hybrids.

Mitochondrial RNA interference in the blue mussel: barriers to overcome

Hubert M¹, Breton S¹

¹Université de Montréal

POSTER SESSION 2 - **P02.027**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The blue mussel (*Mytilus edulis*) is an ideal model for studying the evolution of mitochondrial genomes (mtDNA) and the emergence of novel mitochondrial genes in animals. While animal mtDNA is typically conserved in terms of gene content, notable exceptions exist in bivalves exhibiting doubly uniparental inheritance (DUI) of their mitochondria, such as *M. edulis*. In this species, two novel protein-coding genes have evolved: M-ORF, found in the male-transmitted mtDNA, and F-ORF, present in the female-transmitted mtDNA. Although the functions of these genes remain unknown, they are suspected to be involved in sex determination.

To investigate their roles, RNA interference (RNAi) presents a promising approach by enabling gene silencing in mussel cells. The goal of our research is to develop an RNAi-based method to target mitochondrial genes, such as M-ORF and F-ORF, in blue mussel primary cell cultures. This project poses

significant challenges: *M. edulis* is not a standard model organism in molecular biology, no immortalized cell lines are available, and RNAi must take place within mitochondria, something achieved in only a handful of studies to date.

In this presentation, I will highlight key experimental achievements, including the successful inhibition of the nuclear gene β -actin in *M. edulis* primary cell cultures, and preliminary evidence suggesting the silencing of F-ORF, a mitochondrial gene of unknown function. I will also address current obstacles and propose strategies to overcome them, such as improving the consistency and reproducibility of mitochondrial RNAi. Establishing an effective mitochondrial RNAi protocol in mussels will allow for the study of sex-specific genes like F-ORF and M-ORF, and their potential roles in sexual differentiation in DUI bivalves.

Mitonuclear coevolution as a driver of latitudinal avian speciation trends

Nikelski E¹, Mikkelsen E¹, Weir J^{1,2}

¹University of Toronto, ²University of Toronto Scarborough

POSTER SESSION 2 - **P02.028**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Reciprocal selection between the nuclear and mitochondrial genomes—mitonuclear coevolution—maintains compatibility between nuclear- and mitochondrially-encoded products that associate within the mitochondria during organelle functions. This process is predicted to be an important driver of eukaryotic speciation due to its production of distinct genetic haplotypes that form the basis for severe genetic incompatibilities (“mitonuclear incompatibilities”) and strong reproductive barriers between taxa. However, though mitonuclear incompatibilities have been detected in various systems, the proposed connection between mitonuclear coevolution and speciation remains tenuous. In this study, we investigated the association between these processes by examining mitonuclear coevolutionary dynamics in the context of a major, latitudinal avian speciation trend. Previous research has found that speciation occurs more rapidly in temperate, high-latitude avian systems compared to tropical, low-latitude avian systems across the Americas. These high-latitude avians experience more variable temperature conditions and often participate in long-distance migration which both place additional stress on mitochondrial function. As such, temperate avian systems may experience stronger selection for efficient mitonuclear coevolution compared to their tropical counterparts which could lead to faster speciation rates. To evaluate this hypothesis, we examined patterns of mitonuclear

coevolution across high- and low-latitude avian systems using a comparative genomic approach that incorporated whole-genome sequence data from thirty-nine pairs of closely related avian taxa. We utilized Bayesian codon evolution models and pairwise dN/dS ratio comparisons to assess genomic signals of mitonuclear coevolution across the avian phylogeny and in each species pair respectively. We then compared the genetic patterns associated with temperate and tropical avian pairs to determine whether selection for mitonuclear coevolution varies across latitudes. In our preliminary analyses, we identified strong support for mitonuclear coevolution having occurred across the avian phylogeny and within each avian species pair consistent with theory claiming that mitonuclear coevolution is ubiquitous across eukaryotic organisms. However, we did not find evidence that selection for mitonuclear coevolution differs between temperate and tropical avian systems. This finding implies that mitonuclear coevolution may not be driving the latitudinal gradient in avian speciation though this process may still reinforce the ecological and evolutionary processes that are responsible for this trend. Our research provides valuable insights on mitonuclear coevolutionary dynamics in avian systems, which are applicable across Eukarya, and greater perspective on the potential influence of mitonuclear coevolution in wider evolutionary processes such as speciation.

Mutational Biases and Selection in Mitochondrial Genomes: Insights from a Comparative Analysis of Natural and Experimental Populations of *Caenorhabditis elegans*

Schifano A¹, Berthorsson U, Katju V

¹Uppsala University

POSTER SESSION 2 - **P02.037**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Random mutations display biases in their relative frequencies with important consequences for genome structure and composition. While laboratory studies have provided insights into the spectrum of spontaneous mutations, the laboratory environment of optimal growth conditions may produce its own biases. Hence, further investigation is necessary to determine if laboratory results are truly representative of natural populations. We analyzed the mitochondrial (mtDNA) genomes of 1,524 *Caenorhabditis elegans* natural isolates comprising 550 unique mtDNA haplotypes to investigate patterns of mtDNA evolution in the wild. Ancestral reconstruction was used to polarize 2641 mutations (90 indels, 2,551 SNPs) and the results were compared to mutations identified in experimentally evolved laboratory populations under minimized selection. The frequency of mutations is associated with both codon position and site degeneracy in a manner consistent with strong purifying selection on mtDNA protein-coding sequences. There is significant variation in the per site nonsynonymous and synonymous

substitutions between genes and more particularly genes from ETC complex I are particularly enriched in nonsynonymous substitutions, namely nd-6 and nd-2. The probability of mutation is higher at sites with flanking G/C and the per gene synonymous mutation frequency is associated with GC content at 1st and 2nd base positions in codons, but not with GC content at 3rd base position. Furthermore, the position within a gene influences the base substitution frequency as the 5' and 3' ends of genes have lower synonymous substitution frequency than their centers. We also report the first cases of large heteroplasmic mtDNA structural variants, possibly occurring in natural populations of *C. elegans*, including a suspected duplication of the origin of replication. Although some of the patterns of mtDNA mutational bias are similar between the laboratory and wild populations, we observe significant differences. In particular, transversions typically associated with oxidative damage are less common at four-fold degenerate sites in natural populations than in the laboratory.

Recurrent centromere repositioning in an otherwise stable karyotype of birds

Westerberg I^{1,2}, Ruiz-Ruano F^{1,3,4,5}, Malinovskaya L⁶, Torgasheva A^{4,5,6}, Jönsson K⁷, Segami C⁸, Qvarnström A⁸, Irestedt M⁹, Kawakami T¹⁰, Peona V^{1,9,11}, **Suh A**^{1,3,4,5}

POSTER SESSION 2 - **P02.050**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Centromeres are structural features of chromosomes that act as the primary binding site for the kinetochore during cell division. In birds, like in many other animals, the centromeric DNA is mainly composed of satellite arrays that can expand across megabases. Previous studies have observed that centromeres can shift epigenetically to a different location on the chromosome that may over time accumulate repeats and become established as evolutionary new centromeres (ENCs). ENCs can play important roles in evolutionary processes, such as speciation, but our understanding of the mechanisms driving ENC evolution and how they get established within karyotypes is limited. Because of difficulties in assembling such complex centromeres, reconciling molecular and cytogenetic methods with genomic data is often problematic. Here we investigate a highly syntenic microchromosome of songbirds and its

evolutionary history. We find that two independent centromere shifts have occurred on chromosome 18: one in the ancestor of the families Corvidae and Laniidae, and the second in the sister species, the collared flycatcher (*Ficedula albicollis*) and the pied flycatcher (*F. hypoleuca*). Both shifts resulted in megabase-scale valleys of recombination rate in regions with otherwise high recombination rates. These findings on an otherwise highly collinear chromosome suggest that the ENCs have shifted without other rearrangements. Our results show that our bioinformatics approaches provide a useful tool to study centromeres and ENCs, even in cases where they are largely missing from assemblies. The methods presented in this study will also aid future research of centromere and ENC identification in non-model organisms.

Repeated evolution of all-female populations in facultatively parthenogenetic stick insects

Soldini L¹, Schwander T¹

¹University Of Lausanne

POSTER SESSION 2 - **P02.041**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sexual reproduction is the most common reproductive mode in eukaryotes. However, despite well-supported long-term benefits of sexual reproduction, its short-term benefits – preventing the invasion by asexual mutants – remain poorly understood. One possible explanation for the short-term persistence of sex is that transitions to parthenogenesis are difficult because they require the crossing of fitness valleys. In addition, asexual reproduction may entail short-term fitness costs, but such costs have rarely been quantified in natural populations. Here, we leverage the multiple local transitions to all-female populations (enforcing asexuality) in the facultatively parthenogenetic stick insect *Bacillus rossius* to quantify potential short-term costs associated with transitions between reproductive modes and with asexual reproduction. Females in sexual

populations of this species are able to reproduce via parthenogenesis, but only do so if they remain virgin. Specifically, we sampled individuals from seven pairs of sexual and asexual populations. To quantify potential costs of asexual reproduction, we compared fertility and fecundity between (virgin) asexual and mated sexual females in a common garden environment to identify differences in fitness distributions. To quantify the costs associated with transitions between sexual and asexual reproduction, we further contrasted fitness distributions of virgin sexual females with those of mated asexual ones. Finally, using multiple population pairs within a single species allowed us to disentangle reproductive-mode effects from population-specific ones, and to replicate analyses in an unprecedented manner.

Sexual conflict and the evolution of unconventional sex-roles and male pregnancy in pipefish

Hsiung K¹, Roth O², Böhne A¹

¹Leibniz Institute for the Analysis of Biodiversity Change, ²Marine Evolutionary Biology, Zoological Institute

POSTER SESSION 2 - **P02.046**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Pipefish, alongside seahorses and sea dragons, belong to the teleost family Syngnathidae where males carry broods through specialized skin attachments or brood pouches in varying levels of complexity, a unique form of parental investment akin to pregnancy. Additionally, some members have evolved reversed sex-roles where females compete for access to mates. The evolution of such sex roles is coupled with the evolution of sex-specific traits, which arise from differing selection on males and females. These traits although sex-specific, evolve from one genome shared by both sexes, thus contend with diverging fitness optima between males and females. This creates sexually antagonistic conflict (SAC) which can be alleviated or resolved through sex-biased expression of genes. When sex is genetically determined,

sex specific inheritance of sex chromosomes allow for sex-bias to evolve more freely and accumulate. Furthermore, SAC can achieve full resolution on sex chromosomes when alleles are limited to the sex they benefit. Sex-role reversed pipefish provide the unique opportunity to study sexual selection in females and pregnancy in males. In this study, we looked for signals of sex chromosomes by comparing male and female pool-seq data of two pipefish with sex-role reversal, the straightnose pipefish (*N. ophidion*) and broadnose pipefish (*S. typhle*). We further examined the transcription profiles of four tissues in females and in pregnant and non-pregnant males to understand the contribution of sex-biased expression to sex-specific traits.

Sharks and rays have the oldest vertebrate sex chromosome with unique sex determination mechanisms

Niwa T^{1,2}, Uno Y^{3,4}, Ohishi Y⁴, Kadota M⁴, Nakamura M⁵, Kuraku S^{1,2}

¹National Institute Of Genetics, ²SOKENDAI, Genetics, ³Tokushima University, ⁴RIKEN BDR, ⁵Okinawa Churashima Research Center

POSTER SESSION 2 - **P02.033**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sex determination has been investigated across vertebrate lineages to reveal stepwise evolution of sex chromosomes and diversity of responsible molecular mechanisms. However, these studies hardly encompass cartilaginous fishes deeply isolated from the rest of vertebrates, which hinders the comprehensive view of vertebrate sex determination. Here, we produced chromosome-scale genome assemblies of egg-laying shark species and comparatively investigated genome sequences and transcriptome profiles across diverse cartilaginous fishes. Sex chromosome identification, supported by cytogenetic experiments, elucidated the homology of X chromosomes between sharks and rays as well as an extensively degenerating Y chromosome harboring no male-specific genes. These sex chromosomes scarcely

included orthologs of previously documented sex determining genes. Transcriptomic analyses combined with histology of embryonic gonads revealed female-biased expression of X-linked genes including those implicated in TGF- β and IGF signaling pathways, which are attributed to their incomplete dosage compensation. Our findings indicate that sharks and rays share the oldest sex chromosomes among vertebrates that originated around 300 million years ago and the dosage-dependent sex determination mechanism comprised of distinct molecules from other vertebrates. This study highlights the antiquity of sex chromosomes and uniqueness of sex determination mechanisms in sharks and rays, which advance our understanding of the evolutionary plasticity of vertebrate sex determination.

The evolution of reproductive mode in the *Carassius auratus* complex

Alhaidose R¹

¹Biotechnology Center, Ministry of Municipality

POSTER SESSION 2 - **P02.026**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Abstract: Freshwater fish of the genus *Carassius* are widely distributed across Asia, Europe, and Australia. This includes the *Carassius auratus* complex, a phylogenetically diverse species group with uncertain taxonomy. The *C. auratus* complex is native to Asia but has been introduced to non-native habitats worldwide. It comprises both sexually reproducing diploid individuals and polyploid individuals that predominantly reproduce asexually through gynogenesis. The evolutionary relationships between these different reproductive modes, as well as the invasion history of the various lineages, are poorly understood. A phylogenetic approach using mitochondrial DNA (Cyt b sequence) in combination with six microsatellite markers was employed to investigate the invasion history of different lineages and reproductive modes and to explore the evolutionary relationships between them. The Cyt b analysis was based on sequences from 10 native populations in China and 35 invasive populations in Europe and Australia. Additionally, 1,427 individuals representing 93 populations from China, Europe, and Australia were genotyped at six microsatellite loci to determine their ploidy level and reproductive mode. Phylogenies of three nuclear genes were also used to test two hypotheses regarding the origin of triploid lineages: allopolyploidy and autopolyploidy.

Our results suggest that the invasion of the *C. auratus* complex in Europe occurred through two routes, possibly driven by both historical and anthropogenic events. The microsatellite analysis revealed that 67.19% of individuals were triploids and 33.8% were diploids among the 1,427 individuals

studied. Interestingly, most native populations consisted of a mix of diploids and triploids, with triploids predominating. In contrast, invasive populations exhibited considerable variation in reproductive modes, ranging from purely diploid to purely triploid and mixed populations. Additionally, diploids were dominant in older Eastern European populations, while triploids were dominant in more recently established Central European populations. Both mtDNA and microsatellite markers revealed no separation at the ploidy level, as alleles were shared by both diploid and triploid individuals, and sympatric diploids and triploids shared mtDNA haplotypes in seven highly diverged lineages and sublineages. Furthermore, the high genetic diversity observed in triploid forms may result from propagule vectors, which help mitigate the genetic bottleneck effects typically seen in successfully invasive species. The origin of gynogens could not be conclusively determined using nuclear DNA (Rag1 and S7 genes), as Rag1 analysis suggested an allopolyploid origin, while S7 analysis pointed to an autopolyploid origin.

The *C. auratus* complex provides an ideal model for studying the reproductive traits of polyploid triploids, which holds significant value in animal genetics and reproductive biology.

Key Words: *C. auratus* complex, *C. a. auratus*, *C. a. gibelio*, reproductive mode, gynogenesis, invasive, gene duplication, whole genome duplication, polyploidy, PCR, microsatellites, mtDNA, Cyt b, allele, locus, loci, diploid, triploid, allopolyploid, autopolyploid, nDNA.

The genomic predictability of hybridization: insights from pine contact zones across contrasting environments

Łabiszak B¹, Szczepański S, Wachowiak W¹

¹Adam Mickiewicz University in Poznań

POSTER SESSION 2 - **P02.048**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Hybridization is increasingly recognized as a key driver of evolutionary process that can facilitate adaptive introgression shape the genomic architecture, influence species boundaries, and promote the emergence of novel lineages. In long-lived forest trees with weak reproductive barriers, such as pines, hybrid zones provide natural laboratories for understanding these dynamics. However, the extent to which hybridization outcomes are ecologically repeatable and evolutionarily deterministic remains poorly resolved. Here, we investigate hybrid zone dynamics between Scots pine (*Pinus sylvestris*) and members of the *Pinus mugo* complex across contrasting habitats in Central Europe —taxa characterized by overlapping distributions and frequent natural hybridization. We ask how repeatable is hybrid genomic composition across environments, how selection acts on admixed genomes and whether convergent molecular patterns are evolving in those zones.

Materials and Methods: We sampled over 1700 individuals across 29 populations, including three replicated hybrid zones in Central Europe - two located in peat bogs and one on a sandstone outcrop, capturing variation in ecological context, alongside allopatric reference populations of *Pinus sylvestris*, *P. mugo*, and *P. uliginosa*. Individuals were genotyped at over 7,000 SNP loci using a custom array targeting transcribed and functionally annotated genomic regions. We assessed genetic structure, levels of admixture, and hybrid classification using multivariate and ancestry-based approaches. Hybrid classes were further characterized by estimating genomic ancestry proportions and examining clinal variation across loci. To detect potential targets of selection, we applied complementary genome scan methods and identified outlier loci associated with ancestry and environmental context. These analyses were integrated with chloroplast DNA data to infer the directionality of gene flow. Functional annotations of candidate loci were used to explore the genomic basis of local adaptation and introgression dynamics.

Results: All three hybrid zones exhibited extensive and ongoing hybridization, dominated by advanced-generation hybrids and backcrosses, with few F1 individuals. Genomic structure was strikingly consistent across sites, with asymmetric introgression favoring *P. mugo* ancestry, even in ecologically distinct contexts. Individuals morphologically resembling *P. uliginosa* were genomically indistinguishable from late-generation hybrids, lacking unique ancestry components. Despite strong parallelism in hybrid genomic composition, site-specific patterns of genetic diversity and introgression were evident. Overall, pure *P. sylvestris* and *P. sylvestris*-like individuals exhibited elevated genetic differentiation and higher proportions of loci under selection. Genomic clines revealed non-neutral introgression at several outlier loci, suggesting environment-dependent selection favoring *P. mugo*-derived alleles in certain genomic regions. Patterns of chloroplast inheritance and hybrid index distributions supported recurrent, asymmetric gene flow from *P. mugo* into *P. sylvestris* genomes.

Conclusions: This study provides compelling genomic evidence for the repeatability of hybridization outcomes across replicated hybrid zones in a forest tree system. While hybrid genomic composition was strikingly consistent across sites, local selection imposed differential pressures on admixed genomes—particularly those with predominant *Pinus sylvestris* ancestry in peatland habitats. These findings highlight the interaction between hybridization and ecological selection in shaping hybrid lineage trajectories and influencing the stability of hybrid zones. Our results underscore the importance of ecological context in driving non-neutral introgression and contribute to broader discussions on species boundaries and conservation within the *Pinus mugo* complex. More broadly, this study illustrates the power of replicated hybrid zones as natural experiments for unraveling the genomic architecture of hybridization and its evolutionary consequences in the speciation continu

Unexpected diversity of telomeric repeats in Andrena bees

Findeiß S¹, Klapproth C¹, Stadler P¹

¹Bioinformatics Research Group, Leipzig University

POSTER SESSION 2 - P02.052, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The telomerase based system is a frequently found solution to the end-replication problem of linear chromosomes. The corresponding complex consisting of a non-coding telomerase RNA (TR) and a telomerase reverse transcriptase (TERT) is able to add characteristic telomeric tandem repeats to chromosome ends. Assuming the existence of one TR gene per species, recent studies reported a large diversity in the sequence of telomeric repeats in some insects including a few species of the *Andrena* genus. These ground nesting, solitary bees are widespread and very important pollinators in natural as well as agricultural ecosystems.

I will present the results of our detailed computational analysis of *Andrena* bee genomes and the underlying DNA sequencing data. We found multiple copies

of TR genes forming distinct telomeric tandem repeats in the majority of currently sequenced *Andrena*. Although recently reported for plants, to our knowledge this is the first time this phenomenon has been observed in animals. Findings such as alternating patterns of different tandem repeat sequences at chromosome ends and the experimental evidence of co-expressed presumably functional, i.e. over-represented tandem repeats, and dysfunctional TR gene copies add another, previously unexpected, layer of complexity to the evolution of telomeric repeats.

Although *Andrena* represent one of the largest animal genera only a dozen sequenced genomes are currently available. We are looking for research groups working with *Andrena* bees to jointly study the evolution of telomerase RNA in this genus and beyond.

Age-dependent sex under mutation accumulation

Athreya G¹, Erten E, Kokko H

¹Johannes Gutenberg University Of Mainz

MEETING ROOM 118+119, August 21, 2025, 10:30 AM - 12:30 PM

An often-observed strategy among facultatively sexual organisms is to invest in (costly) sex only when in poor condition — a scenario usually caused by environmental change, population crowding, or other external cues. Yet, a major determinant of organismal condition is internal: mutation accumulation with age. Whereas somatic mutations can result in deteriorated organismal condition, germline mutations strongly impact the fate of a lineage, as they can be transmitted to the offspring to varying degrees, depending on the reproductive mode. As such, switching between reproductive modes based on germline state can help maximize the benefits of sexual reproduction while minimizing its costs. However, an organism cannot always accurately measure the state of its germline based on its somatic condition. In such cases, age might emerge as a reliable cue due to its correlation with mutation load. Such age-dependent plasticity in reproductive mode has previously been described empirically in *Hydra oligactis*. In this talk, I will describe a mathematical model constructed to understand the population and evolutionary dynamics of three reproductive strategies: sexual reproduction when young followed by

asexual reproduction when old (sex only when young), asexual reproduction when young followed by sexual reproduction when old (sex only when old), and obligate sex. We show that all strategies can all persist in isolation, under different parameter regimes. The two age-dependent facultative sex strategies are by far the dominant evolutionary outcomes due to an "exploitation" effect that operates when they interact with obligate sexuals, allowing them to enjoy the benefits of sex (via fusion with gametes produced by the exploited) without paying as much of a cost. This leads to three outcomes under different parameter combinations: (i) over-exploitation leading to the extinction of a strategy that is viable in isolation, (ii) priority effects where evolutionary outcome is determined by whether a strategy is the resident or not, and (iii) sex only when old being the dominant outcome. These results contribute to our understanding of the evolution of sex, demonstrating not only the viability of age as a cue for facultatively sexual organisms, but also its inherent differences compared to condition-based cues.

Characterizing the germline-restricted chromosome in a hybrid-species complex of sparrows

MEETING ROOM 118+119, August 21, 2025, 10:30 AM - 12:30 PM

New species can emerge from hybridization without a change in chromosome numbers, and such a new species is a type of hybrid species. The evolution of the hybrid genomes offers immense opportunities to study genetic (in)compatibility, adaptation, and speciation. A recently discovered feature of the over 5000 songbird species—the germline-restricted chromosome (GRC)—is present only in germline cells and absent from somatic cells, meaning it has been overlooked in most songbird genomic studies to date. Interestingly, the GRC typically follows maternal inheritance patterns, with occasional cases of paternal inheritance. Furthermore, its copy number in females vs. males are reminiscent of an XX/XO sex chromosome system. These characteristics make it particularly intriguing in the context of the emergence and evolution of selfish genetic elements, as well as potential genetic incompatibilities with other maternally inherited elements, such as the mitochondrial genome.

In this study, we investigate the GRC in a young hybrid songbird (~5,800 years old), the

Italian sparrow *Passer italiae*, and its two parental species, the house sparrow *P. domesticus* and the Spanish sparrow *P. hispaniolensis*. Using a combination of PacBio HiFi long reads, Nanopore ultra-long reads and TELL-seq linked reads, we characterized the gene content, diversity and mutation rate of the GRC across species to explore its evolutionary dynamics in the context of hybrid speciation. Our three sampled Italian sparrows show mitochondrial haplotypes similar to those of the parental house sparrow. As expected from the typical matrilineal inheritance, the Italian sparrow GRCs appear to have also arisen from house sparrow, however, followed by multiple episodes of complex structural mutations highlighting how much faster than the rest of the genome the GRC evolves. Our findings provide critical insights into the role of the GRC in genome evolution, and its potential relationship with the formation and stability of hybrid species. This work establishes a novel model system for studying the evolutionary impact of germline-specific chromosomes in birds.

Disentangling the genomic architecture of sex chromosomes in an androdioecious species with two mating types

Contreras Garrido A¹, Billiard S¹, Monniaux M¹, Vekemans X¹, Mazoyer C¹, Gode C¹, Vernet P¹, Saumitou-Laprade P¹, Castric V¹
¹CNRS

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Androdioecy is a rare reproductive system in which both male individuals and hermaphrodites coexist within a species. The requirements for its emergence and long-term stability are thought to be strict, hence, it is very uncommon among living organisms. An exception is found in the Oleaceae plant family, which contains a large subset of all known androdioecious species. The evolutionary puzzle of androdioecy in this family was illuminated by the discovery of a highly conserved self-incompatibility (SI) system in which hermaphrodites are divided into just two cross-compatible groups. Male individuals can bypass this SI barrier, giving them a direct reproductive advantage that offsets the loss of female function. This shift alters the dynamics of sexual antagonism

between the reproductive morphs and may influence the evolutionary path of sex chromosomes. Recent efforts have revealed the hemizygous structure, mechanism, and conservation of this SI system across the family. To further investigate these dynamics, we mapped, assembled, and annotated the sex chromosome of the androdioecious *Phillyrea angustifolia*. Our analysis revealed a relatively small, yet extensively rearranged, sex-determination region. Ongoing work is focused on understanding how this region evolved from its autosomal ancestor and how it has developed epistatic interactions with the genomic region responsible for self-incompatibility.

Evolution of divergent male and female mitochondrial genomes in a basal protobranch bivalve *Yoldia hyperborea*

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Doubly uniparental inheritance (DUI) of mitochondrial DNA (mtDNA) is a mode of mtDNA transmission whereby the male mitogenome is inherited predominately by males and the female mitogenome is inherited by females. DUI is unique to bivalve mollusks and has been identified in all major bivalve clades, including Protobranchia, the most basal bivalve subclade. While this system has evolved in bivalves independently at least tens of times, the mechanics of this process is poorly understood. Here, we focus on the early stages of divergence of male and female mitochondrial genomes by sequencing them in a basal Protobranchia species *Yoldia hyperborea* where they are characterized by one of the lowest known level of divergence, suggesting a recent origin of this system. Despite the high relatedness of female and

male genomes, we find that they have undergone rapid divergence both on the sequence and the structural level, including an origin of a novel gene in the male genome. This novel gene is functional, as evidenced by the fact that it is transcribed and is subject to purifying selection. Additionally, the female mitogenome contained a duplicated cassette containing the cytochrome b gene, resulting in two different transcripts in female gonads both of which are subject to purifying selection, although their transcription levels differ by two orders of magnitude. These results showcase the rapid adaptation of female and male mitochondrial genomes soon after their separation in a double uniparental inheritance system, akin to that observed in evolution of sex chromosomes.

Evolutionary drivers and consequences of monogeny: a unusual reproductive system in fungus gnats

Henot M¹, Duncan F¹, Baird R², Ross L¹

¹University Of Edinburgh, ²Whitehead Institute, MIT

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Black-winged fungus gnats (Family: Sciaridae) are a group of Dipteran insects extraordinarily unique in their reproduction. They exhibit maternal genetic sex determination, where maternal genotype - instead of zygotic genotype - determines zygotic sex. Even more unusually, some species are monogenic, in which females produce offspring of only one sex. Other fungus gnat species are digenic and produce mixed-sex broods, but the intra-family sex ratio is often far from 50/50. These mating systems have not just evolved once, but experience extensive turnover within the clade, with both strategies being found in pairs of sister species.

Being a significant departure from the long-held dogma of stable, ancient and zygotic genetic sex determination systems, fungus gnats provide novel insights into general principles. For one, a central debate in this field is the evolution of sex-determining regions, for which fungus gnats provide a unique context for study. The genetic basis of maternal sex determination is a X-linked inversion heterozygous in female-producing females. This supergene seems to have

arisen independently in each instance of monogeny, and harbours intraspecific polymorphism. Does this non-recombining region accumulate deleterious mutations, or facilitate alleles advantageous for specialisation into female-production? While the evolutionary dynamics of this inversion is likely a key factor for the instability of monogeny, it also provides an intriguing parallel to the evolutionary drivers and outcomes of zygotic genetic sex determination regions.

To understand the impacts of specialising into single-sex production, and its interplay with mating system turnover, I focus on a model species *Bradysia coprophila*. I present findings on gene expression and phenotypic divergence between reproductive morphs, suggesting possible specialisation under selection. I also outline ongoing comparative studies of a closely-related species with independently-evolved monogeny and supergene polymorphism. This intriguing system broadens our understanding of the diversity of sex determination systems, and acts as an informative intra-sex analogy for sex chromosome evolution.

How parasites can influence recombination in an almost fully parthenogenetic population : the case of the Bedegar gall wasp.

Mozhaitseva K, Pourtoy A, Miquel M, Vincent X, **Branca A**¹

¹Evolution Genome Comportement Ecologie, CNRS Université Paris Saclay, IRD UMR 247

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Cynipoidea are a group of hymenopterans that exhibit a wide diversity of reproductive strategies. Most species classically reproduce through haplodiploidy, typical of hymenopterans, where males are haploid, resulting from arrhenotokous parthenogenesis, and females are diploid, resulting from sexual reproduction. However, some species present different strategies, notably thelytoky, where males are typically absent and females can produce female offspring without reproduction. Even thelytoky can occur in various ways, either during meiosis (automixis) or without meiosis (apomixis). Two distantly related clades have even evolved cyclical parthenogenesis, where two generations are produced alternately each year: one thelytokous and one sexual. The rose bedeguar wasp, *Diplolepis rosae*, is a cynipid wasp that induces galls on wild roses. In many populations across Europe,

due to thelytoky, very few males are observed emerging from the galls. Consequently, the species shows a high level of homozygosity. However, we found that among two divergent populations, one retains some genome-wide heterozygosity. Selection scans could show that genes related to male function are under negative selection in the more diverse population and relaxed selection in the other population. This is potentially indicative of a selective pressure to maintain the ability to produce males. We indeed found that the more genetically diverse population also experienced much less parasitic pressure than the homozygous one. The persistence of highly homozygous lineages could be due to higher fertility, as shown by a tendency to produce larger galls. Our study shows how parasite pressure could potentially influence the maintenance of diverse genetic systems.

Stepwise recombination suppression around the mating-type locus associated with a diploid-like life cycle in *Schizothecium* fungi

De Filippo E¹, Chahine E¹, Legendre--Despas J¹, Snirc A¹, Labat A¹, Michel P¹, Grognet P², Gautier V³, Levert E^{1,3}, Lalanne C³, Silar P³, Giraud T¹, Hartmann F

¹Écologie, Société, et Évolution, CNRS, Université Paris-Saclay, AgroParisTech, ²Université Paris-Saclay, CEA, CNRS, Institute for Integrative Biology of the Cell, ³Laboratoire Interdisciplinaire des Énergies de Demain, Université Paris Cité

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Recombination suppression often evolves around sex-determining loci and extends stepwise, resulting in adjacent regions with different levels of divergence between sex chromosomes, called evolutionary strata.

In Ascomycota fungi, evolutionary strata around the mating-type locus have only been found so far in few species, all with a rare diploid-like life cycle, known as pseudo-homothallic species, characterized by mycelia carrying nuclei of both mating types. In contrast, no recombination suppression has been observed in Ascomycota fungi with haploid-like life cycle and heterothallic genetic systems (with mycelia colonies of a single mating type each).

We investigated the evolution of recombination suppression in a clade of dung fungi encompassing 16 pseudo-homothallic and three heterothallic sibling species from the *Schizothecium* genus (Ascomycota, Sordariales).

The analysis of genetic divergence based on genome sequencing indicated recombination suppression around the mating-type locus in all studied pseudo-homothallic species. The non-

recombining region ranged from 600 kb to 1.6 Mb and harbored multiple evolutionary strata, varying in size and number among species. The separation of alleles associated with alternative mating types in gene genealogies, the high linkage disequilibrium and an inversion in one species altogether supported the lack of recombination in the mating-type locus proximal region in pseudo-homothallic species. The lack of trans-specific polymorphism suggested multiple independent events of recombination suppression or the occurrence of rare events of recombination or gene conversion. Progeny analyses showed the occurrence of recombination close to the mating-type locus in heterothallic strains.

We thus revealed multiple and likely independent evolutionary strata, associated with an extended diploid-like stage in *Schizothecium* fungi, which supports the hypothesis of an association between a pseudo-homothallic genetic system and recombination suppression around the mating-type locus and provides a good model for research on sex-related chromosome evolution.

The cheater-driven evolution of reproductive division of labour

Devlin D¹, R.D. Ganley A¹, **Takeuchi N**¹

¹University Of Auckland

MEETING ROOM 118+119, August 20, 2025, 10:30 AM - 12:30 PM

Background: Reproductive division of labour (RDL), where sterile 'helpers' assist specialised 'reproducers' in propagating genetic information, has repeatedly evolved across vastly different biological scales, from molecules to multicellular organisms. Traditionally, the evolution of RDL has been thought to require high relatedness between interacting individuals, as it entails altruism — helpers foregoing self-reproduction to benefit reproducers. Contesting this traditional view, we present a model predicting that RDL evolves when relatedness is sufficiently low.

Model: We constructed an individual-based model of evolving multicellular organisms. The model consists of a population of competing organisms. Each organism consists of a population of cells that divide and die. Each cell possesses a finite amount of resource to allocate between cell division and somatic function, with the allocation strategy being evolvable. Allocating to cell division increases the cell's relative fitness within the encompassing organism, whereas allocating to somatic function can increase the fitness of all cells in the same organism — constituting a trade-off between individual and collective benefit. Every cell exists in one of two interconvertible states with evolvable conversion rates. These cell states are associated with independent resource allocation strategies, which are initially identical but may diverge through evolution. Consequently, a cell may vary its resource allocation depending on its state.

Results: Simulations show that RDL evolves when relatedness is initially sufficiently low. The evolved RDL involves cell-state-dependent resource allocation, where cells in one state (helpers) allocate their resource to somatic function, whereas cells in the other state (reproducers) allocate it exclusively to cell division. Crucially, RDL causes an increase in relatedness among cells, thereby protecting organisms against the evolution of cheater

cells — cells that prioritise individual gain over collective benefit. This protection arises from two additional features involved in the evolved RDL. First, reproducer cells convert to helper cells, but not vice versa — i.e., conversion is irreversible. Second, reproducer cells are less abundant than helper cells. These features restrict the transmission of genetic information to a limited number of reproducer cells per organism, thereby reducing the within-organism effective population size from which cheaters may arise. We show that RDL evolves to provide protection against cheater evolution under both accelerating and decelerating returns on resource investment, demonstrating that this evolutionary outcome is robust to the shape of the trade-off curve.

Conclusions: Our model shows that RDL evolves as an evolutionary strategy to elevate relatedness and mitigate the threat of cheater evolution. This cheater-driven perspective predicts that RDL evolves when relatedness is low because the protective benefit of RDL rises with the risk of cheater evolution. Therefore, while our model agrees with kin selection theory in predicting that high relatedness coincides with RDL, it challenges the prevailing view by predicting that high relatedness is a consequence, rather than a cause, of RDL evolution.

Our model offers a general mechanism to explain RDL evolution compared to previous models that rely on system-specific mechanisms. For example, a model of the green alga *Volvox* predicts that RDL improves locomotory efficiency by enabling a more hydrodynamic body design. Such an explanation is unlikely to apply in general. In contrast, our model predicts that RDL is favoured whenever cheaters can prosper — a condition common across diverse biological systems and scales. This broad applicability makes our model a more general framework for understanding the evolution of RDL.

The conundrum of germline restricted chromosomes in black winged fungus gnats (Diptera)

Hodson C¹, Bliznina A², Ebdon S², Pomiankowski A¹, Jaron K²

¹University College London, ²Wellcome Sanger Institute

MEETING ROOM 118+119, August 21, 2025, 10:30 AM - 12:30 PM

Most sciarids have germline restricted chromosomes (GRCs), which are present in germ cells but eliminated from somatic cells during embryogenesis in a conserved way. Other aspects of GRC evolution, however, seem less conserved. Notably, cytological evidence shows that the GRCs vary in size and number across the sciarid clade, and during meiosis GRCs have different patterns of transmission compared to other chromosomes in the genome and GRC transmission may vary in different individuals. We are currently working to understand, with both cytological and genomic analyses, how GRCs in sciarids evolved and how much GRC variation there is among and within species. So far, we have focused primarily on three sciarid species which can be kept in the lab: *B. coprophila* (2 GRCs), *B. impatiens* (1 GRC), and *Lycoriella ingenua* (2 GRCs). We generated chromosome level genomes for the germline of these species, and are complementing this dataset with additional genomic and

cytological evidence of GRC behaviour. In all three species, we see evidence for an origin of GRCs through introgression (likely via interspecific hybridization) from a gall gnat (Cecidomyiidae). Apart from evidence of their common origin, the five GRCs we sequenced lack large-scale gene conservation or synteny. This finding is intriguing for a number of reasons. We expected GRCs to carry some conserved genes, either for transmission or related to their germline location. However, we find that gene evolution on these chromosomes is extraordinarily dynamic, even between closely related species. Furthermore, GRCs are expected to recombine during female meiosis in species that carry two of these chromosomes. The fact that we sequence two distinct GRCs in species with two of these chromosomes suggests that these chromosomes may not recombine, suggesting a need to re-evaluate hypotheses of how these chromosomes are evolving.

The evolution of non-hybrid asexual reproduction in neotropical night lizards (*Lepidophyma* spp.)

MEETING ROOM 118+119, August 21, 2025, 10:30 AM - 12:30 PM

Reptiles are the only vertebrate clade in which true parthenogenesis, a form of asexual reproduction which does not involve male sperm, occurs. Many reptile species, including several birds, have been known to facultatively reproduce parthenogenetically. Although rare, most described all-female obligate parthenogenetic lineages are of hybrid origin, producing unreduced eggs using premeiotic endoreplication. Thus, all offspring are genetically identical to their mother. However, there is a unique vertebrate lineage where obligate parthenogenesis evolved without hybridisation - *Lepidophyma* night lizards from Central America. While most of the species in this genus are considered sexual, both facultative and obligate parthenogenesis occur in some species. Using both cytogenetic and genomic approaches, we studied the facultative parthenogenetic species *Lepidophyma smithii*, the sexual but regionally obligate

parthenogenetic *L. flavimaculatum* and the all-female *L. reticulatum*. We explore meiotic mechanisms and genomic heterozygosity underlying parthenogenesis in this genus. On top of that, we discovered diploid-triploid mosaicism in several individuals of *L. flavimaculatum*. We also assembled the genome of *L. reticulatum*, providing valuable insights into the evolution of parthenogenesis in vertebrates. We propose a novel mechanism where obligate parthenogenesis in *Lepidophyma* is not based on premeiotic endoreplication but instead evolved from the fixation of facultative parthenogenesis underpinned by fusion automixis, where an egg cell fuses with the polar body during meiosis. Altogether, we provide cytogenetic and genomic insights into the evolutionary mechanisms of the only non-hybrid origin of parthenogenesis in vertebrates.

When sex stops, genes change: ending sexual conflict alters gene expression

Defendini H¹, Prunier-Leterme N¹, Robin S¹, Lameiras S², Baulande S², Simon J¹, **Jaquiéry J¹**

¹UMR 1349 IGEPP, INRAE, Institut Agro, Université de Rennes, ²Institut Curie, PSL University, ICGex Next-Generation Sequencing Platform

MEETING ROOM 118+119, August 21, 2025, 10:30 AM - 12:30 PM

Sexual conflict can arise because males and females, while sharing most of their genome, can have different phenotypic optima. Sexually dimorphic gene expression may help reduce conflict, but the expression of many genes may remain sub-optimal due to unresolved tensions between the sexes. Asexual lineages lack such conflict, making them relevant models for understanding the extent to which sexual conflict influences gene expression. We investigate the evolution of sexual conflict subsequent to sex loss by contrasting the gene expression patterns of sexual and asexual lineages in the pea aphid. Although asexual lineages of this aphid produce a small number of males in autumn, their mating opportunities are

limited because of geographic isolation between sexual and asexual lineages. Therefore, gene expression in parthenogenetic females of asexual lineages is no longer constrained by that of other morphs. We found that the expression of genes in males from asexual lineages tended towards the parthenogenetic female optimum, in agreement with theoretical predictions. Surprisingly, males and parthenogenetic females of asexual lineages over-expressed genes normally found in the ovaries and testes of sexual morphs. These changes in gene expression in asexual lineages may arise from the relaxation of selection or the dysregulation of gene networks otherwise used in sexual lineages.

POSTER SESSION 2 - **P02.063**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Small and isolated populations experience unique evolutionary dynamics shaped by selection, phenotypic plasticity, and potentially strong genetic drift. Understanding how multiple traits evolve in such populations is important for predicting their adaptive potential in response to climate change. Here, we investigate the divergence of metabolic, morphological and growth-related traits in two allopatric populations of Alpine charr (*Salvelinus umbla*) isolated for a century in ecologically contrasting lakes. We combined a common garden experiment with a quantitative genetic approach to disentangle the relative contributions of genetic divergence and plasticity to phenotypic differentiation. Population genetic differentiation was estimated using microsatellite markers and we applied Q_{st} - F_{st} comparisons to test whether phenotypic divergence resulted from adaptive (e.g., selection) or neutral (e.g., drift) processes. Our results revealed low neutral genetic differentiation ($F_{st} = 0.017$), suggesting limited drift, and Q_{st} - F_{st} comparisons indicated signatures of

divergent selection for several traits. Adults showed an important divergence in body shape and growth trajectories, potentially underlying a high environmental plasticity due to resource availability and temperature variation. In juveniles reared under common garden conditions, we found a substantial differentiation in metabolic rate, its allometric scaling and morphological traits likely related to trophic or visual functions (as indicated by an elevated Q_{st}), suggesting early-life divergent selection. These differences may reflect adaptation to distinct thermal regimes for metabolic traits, and to contrasting resource availability or foraging demands for morphological traits. This study provides empirical evidence of rapid trait evolutionary divergence in isolated populations, highlighting the role of both selection in evolutionary trajectories and phenotypic plasticity to phenotypic differentiation across environments. These findings highlight the importance of small, isolated populations in understanding adaptive potential in a changing climate.

A genomic toolkit reveals severe inbreeding depression in Seychelles warblers

Lee K¹, Bartleet-Cross C¹, Dong S², Gonzalez S², Pinto A³, Lee C³, Komdeur J², Richardson D³, Dugdale H², Burke T¹

¹University of Sheffield, ²University of Groningen, ³University of East Anglia

POSTER SESSION 2 - **P02.094**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Inbreeding threatens wild populations that have drastically shrunk. We test the effect of inbreeding on fitness in a recently bottlenecked population of Seychelles warblers (*Acrocephalus sechellensis*).

Materials and Methods: We have assembled the genomic toolkit for this species. This comprises a chromosome-level reference genome and millions of genome-wide markers acquired by low-coverage whole-genome sequencing followed by imputation, for around 2000 individuals. Genomic data accompanies three decades of detailed life-history traits measured from long-term monitoring of the island-enclosed population.

Results: With this data, we verify that the size and timing of the bottleneck coincides with European colonisation of Seychelles eroding

Ne to twelve, only nine generations ago. We find significant evidence of inbreeding depression, using genomic metrics of inbreeding and lifespan and lifetime fecundity as proxies of fitness.

Conclusions: Even island-living species, such as Seychelles warblers face inbreeding depression when population size shrinks. This suggests other wild populations may face the same and our genomic toolkit, and its scripts may help other researchers create their own toolkit to investigate this. In Seychelles warblers, we suggest evaluating the benefits of outcrossing with individuals from other island populations to prevent inbreeding depression. Our new genomic toolkit also allows for a range of other subsequent analyses including quantifying adaptive potential and loss of genetic diversity.

Behavioral adaptations at key genes in a small and isolated bear population facilitate coexistence with humans.

POSTER SESSION 2 - P02.086, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The Apennine brown bear (*Ursus arctos marsicanus*) inhabits today a limited area in central Italy, where only around 50 bears survive in a human-dominated landscape. Once connected with the other European populations, it has been isolated for the last few thousand years, during which time direct persecution and land-use change caused a continuous population decline. This has led to marked genetic differentiation as well as morphological and ecological divergence. Interestingly, the Apennine brown bear is generally described as less aggressive compared to other populations, such as the European (*U. a. arctos*) and the North American brown bear (*U. a. horribilis*). While strong genetic drift has certainly shaped the genetic diversity of this endemic population, we hypothesized that prolonged environmental sharing with humans and direct persecution of the more aggressive bears may have driven the evolution of behavioral adaptations in the Apennine brown bear.

To test this hypothesis, we compared whole genome sequences of Apennine brown bears with bears from Slovakia, Alaska, and Canada as controls for larger populations with a documented history of aggression toward humans. Three complementary genome-scan methods were used to identify signatures of divergent selection in the Apennine brown bear. Additionally, in-silico analysis of highly differentiated variants was conducted to help elucidate the molecular mechanism possibly involved in the determination of a less aggressive phenotype.

We identified 566 candidate genes under selection in at least one of the genome scans. Functional enrichment analysis revealed a significant overrepresentation of genes associated with the human phenotype "overfriendliness" (seven outlier genes, $p=0.038$), suggesting a signal regarding behavioral mechanisms. Among the candidate genes, we identified ten additional genes known to influence behavior or neurological development in other species with tamer or domesticated forms.

The majority (14/17) of these behavior-associated genes showed highly differentiated intronic SNPs between the Apennine brown bear and the control populations, many of which are predicted to affect mRNA maturation via alternative splicing. In particular, one gene (SLC13A5) showed potential for exon skipping, and many genes were predicted to carry variation at splicing factor binding sites. This finding could imply that alternative splicing plays a role in determining the Apennine brown bear specific behavioral phenotype.

Our study suggests that the Apennine brown bear population has been subjected to human-mediated selection for a less aggressive behavior, likely through the historical elimination of the animals that were more prone to attack humans. Given the positive attitude of all the stakeholders sharing the land with this large mammal today, it is possible that this phenotypic trait has increased the chances of population persistence and human-bear coexistence.

Beyond panmixia: Disentangling structure and recent declines in a threatened humpback whale population using SFS- and LD-based demographic inferences

Le Gouellec M¹, Laso-Jadart R¹, Saloma A³, Jung J^{1,2}, Ragsdale A⁴, Mona S¹

¹ Institut de Systématique, Évolution, Biodiversité (ISYEB), Muséum National d'Histoire Naturelle, CNRS, Sorbonne Université, EPHE-PSL, ² Station Marine de Dinard du Muséum National d'Histoire Naturelle, ³Cétamada, ⁴Department of Integrative Biology, University of Wisconsin-Madison

POSTER SESSION 2 - P02.106, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Inferring the recent demographic history of a population from genetic data is a major challenge, particularly for wild species with poorly known population structure. This issue is exemplified in baleen whales, which experienced a drastic decline due to industrial whaling over the past two centuries. Among them, humpback whales (*Megaptera novaeangliae*) are estimated to have undergone a tenfold bottleneck over centuries of intensive whaling. Yet, the extent to which this recent change in census size has influenced the dynamics of genetic diversity remains unclear.

Several studies have attempted to quantify the genomic impact of whaling on different baleen whale populations, excluding humpback whales. However, these analyses often focus on a single sampling site and assume panmixia, a strong hypothesis that may lead to spurious demographic inferences when population structure is present. Detecting the consequences of whaling faces two major challenges. The first is to determine whether the population under study is better described by a panmictic or a structured model. The second is to successfully detect very recent demographic changes.

Here we assess the strengths and limitations of various computational tools to infer recent demographic events using the Madagascar humpback whale population as a case study. We use a large set of whole-genome re-sequenced individuals and extensive simulations to compare the results of demographic inferences based on either panmictic or structured scenarios, implementing either site frequency spectrum (SFS) based or linkage disequilibrium (LD) based inferential framework.

When applied to Malagasy humpback whale data, panmictic models reveal a strong bottleneck occurring only a few generations ago independently of the inferential framework used. These results are consistent with the historical records of whaling

and have been reported in another species, the fin whale, using SFS based approaches. However, when comparing structured vs panmictic models in a likelihood framework, SFS methods reveal that the former were statistically more supported than the latter, but did not recover a recent bottleneck. Conversely, LD-based modelling recovered a recent change in population size even in structured scenarios, yielding higher likelihood than panmictic models. To shed more light between the different outcomes of SFS vs LD modelling particularly concerning recent time variation, we performed a simulation-based study varying the time and intensity of the bottleneck in both panmictic and structured scenarios. A grid search over the two parameters suggested that LD-based inferences are more effective for recovering very recent signals (confirming hints from theoretical studies), and more capable of distinguishing changes in effective population size from changes in population structure.

In summary, SFS based approaches may overlook recent signature of population size change if only focusing on the likelihood distribution of different scenarios. This may have tremendous consequences especially in the field of conservation genomics. LD-based methods, still at their infancy when applied to non-model species, appear to be a promising alternative but need careful testing on a wider set of scenarios. Their validity should be also assessed when focusing on deeper temporal events. We believe that combining different inferential approaches will be warranted in the future to establish robust species-specific demographic scenario, as exemplified by our results on the humpback whale population from Madagascar. The correct understanding of the demography of a species is essential to predict the evolution of consanguinity and mutational load, which is of particular interest to improve the management of endangered population.

Colonisation costs drive weak purifying selection in island rails

Wanders K¹, Oguzhan Z¹, Kimball R², Braun E², Nielsen S¹, Øksnebjerg D¹, Graves G³, Rahbeck C¹, Chen G⁴, Feng S⁴, Gilbert M¹, Zhang G⁴, Hosner P¹

¹University of Copenhagen, ²University of Florida, ³Smithsonian Institution, ⁴Zhejiang University

POSTER SESSION 2 - P02.072, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Insular (island-limited) populations typically show signatures of weak purifying selection, indicating small effective population sizes compared with those on the mainland. However, the source of these patterns is often unclear – they may be residual signatures from a brief period of inefficient selection associated with island colonisation, or they may reflect longer-term range limitations for insular species. Here we disentangle these hypotheses by analysing the drivers of variation in mitochondrial evolutionary rates (dN/dS) among 46 rails (Aves: Rallidae). We find that insular rails with short terminal branches (indicating recent island colonisation) have highly elevated mitochondrial dN/dS. In contrast,

rails representing more ancient island colonisations have dN/dS ratios that are indistinguishable from mainland/widespread species. Furthermore, we find that island size and the time since human settlement are unrelated to dN/dS ratio variation. Finally, we show that the elevated mitochondrial dN/dS of recently founded island rail populations is driven by generally weak purifying selection, as opposed to positive selection limited to a small number of sites. Taken together, these results indicate that insular rails suffer a high initial cost of island colonisation and undergo a period of inefficient selection, but that there is little detectable impact of longer-term range limitations.

Comparative Genomics in an Ex Situ Gorilla Population

POSTER SESSION 2 - P02.105, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Conservation genomics has emerged as a crucial discipline for understanding and preserving biodiversity, especially for critically endangered species such as gorillas. Gorillas are classified into two distinct species: western and eastern. Each species is subdivided into two subspecies: western gorillas into the western lowland and Cross River gorillas, and eastern gorillas into the eastern lowland and mountain gorillas. All four subspecies are labeled as endangered (mountain gorillas) or critically endangered (western lowland, eastern lowland, and Cross River) by the IUCN.

We analyze 248 gorilla whole genomes (93 publically available, and 155 newly sequenced). Of the 248 genomes, 205 belong to the captive western lowland gorillas, the main captive population studied in this project, including 169 individuals born in captivity and 36 born in the wild. We also include 1 captive Cross River and 2 captive eastern lowland individuals. Moreover, a small subset of the 248 genomes belongs to wild individuals from the eastern lowland (10 individuals), Cross River (18 individuals), and mountain gorilla (12 individuals) subspecies, included for comparative genomic purposes.

In this work we illustrate patterns of ancestry, genetic diversity, relatedness, and inbreeding of captive living gorillas housed primarily in European Zoos, to add information that could help in conservation strategies. Furthermore, we analyze the relatives of “Floquet de Neu” gorilla to determine which ones carry the autosomal-recessive mutation responsible for Floquet’s albinism.

Whole genome samples in this study are obtained from various sources, including whole blood, hair, and blood stored on FTA cards. Whole blood samples exhibit higher levels of endogenous DNA compared to the other types. Additionally, genomes derived from blood

samples show significantly higher mean coverage (~22X) than those from hair and FTA cards (~10X). This variation in coverage is accounted for in downstream analyses.

The findings reveal distinct clustering between western and eastern gorilla species, as seen in previous studies, with evidence of admixture among western lowland individuals born in captivity. This admixture likely results from breeding between individuals from the same subspecies but originating from geographically distant wild populations (e.g., different countries).

There is a noteworthy degree of relatedness observed among the analyzed captive population of Western Lowland gorillas (a total of 179 pairs of first-degree relatives are found within the western lowland captive population). Moreover, the predicted heterozygosity value of the analyzed western lowland individuals is higher compared to those of the examined eastern lowland and mountain gorillas, in agreement with previous studies. Finally, when discussing the DNA of Floquet’s relatives, seven individuals are found to carry, in heterozygosity, the mutation responsible for Floquet’s albinism.

The implications of this study for the EEP (European Endangered Species Programme) provide new insights into the specific genetic information of all captive living gorillas in European zoos.

Additionally, clarifying the degrees of relatedness among these individuals is valuable for future comparisons and updates to the current Studbook—a comprehensive record tracking the genetic lineage, demographics, and history of each individual gorilla. This clarification will support the planning of effective breeding programs to reduce inbreeding within the population.

Conservation genomics in action: Advancing conservation of the small populations of threatened Australian flora

Yap J¹, Rossetto M¹

¹Botanic Gardens of Sydney

POSTER SESSION 2 - **P02.091**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Flora in Australia is highly diverse yet exists within highly fragmented landscapes. Native plant populations face numerous threats, including from urbanisation, altered fire regimes, disease, and invasive weeds and pests. While various conservation efforts are in place, significant gaps in species-specific knowledge hinder development and implementation of effective conservation strategies.

Genomic technologies are transforming plant conservation by offering crucial insights into taxonomic resolution, genetic diversity, population viability and evidence-based management strategies. Streamlined workflows make the integration of genomics into conservation programs feasible, and the growing body of genomic studies highlights resulting practical applications, including ensuring limited conservation resources are allocated properly to maximise conservation outcomes at minimal cost.

At the Botanic Gardens of Sydney, a highly applicable conservation genomics workflow is supporting the conservation of over a quarter of threatened plant species in New South Wales, Australia. This includes a range of species facing different threats and requiring tailored conservation approaches.

The workflow is designed to address target questions to empower threatened species officers to make informed, evidence-based decisions on conservation strategies aimed at supporting long-term species survival.

To illustrate the utility of this workflow, we present genomic findings on a selection of species with varying conservation status and causes of decline. These examples demonstrate diverse processes influencing small, vulnerable populations:

- *Astrotricha crassifolia* - a species with two highly disjunct small populations, each consist of plants of varying growth habits
- *Eidothea hardeniana* - a narrow endemic species restricted to a single location, recently impacted by altered fire regimes
- *Rhodamnia rubescens* – formerly widespread but now severely impacted by Myrtle Rust

These case studies exemplify how genomics can inform and tailor management interventions, ultimately enhancing the effectiveness of conservation planning across diverse ecological contexts.

Differentiation in host plant performance among beetle populations – adaptation to local plant community?

Winslott E¹, Karlsson Green K², Tarka M¹

¹Lund University, ²Swedish University of Agricultural Sciences

POSTER SESSION 2 - **P02.087**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Host plants are essential for the fitness of phytophagous insects, and spatial variation in host plant availability may lead to local variation among populations through adaptive evolution or phenotypic plasticity. Studying intraspecific variation in host plant adaptation can give us insights into local degrees of specialization and potential for adaptability to environmental changes, such as shifts in host plant community.

The green tortoise beetle *Cassida viridis* is a phytophagous specialist that utilizes a few plant species within the Lamiaceae family as hosts. The host plants are vital to the beetle's life cycle since they mate, oviposit, and feed at the host plants. Therefore, the distribution of plants restricts *C. viridis* to small patches in the heterogeneous landscape. We studied how host plant performance varied in four Swedish *C. viridis* populations, which differ in host plant compositions ranging from a single plant species to a mixture of species. Two of the populations sampled are located 30 km apart in Skåne, southern Sweden, while the other two are situated in Halland and Närke, approximately 200 km and 300 km north of the Skåne populations, respectively.

We collected oothecas (egg capsules) from the field and installed them in controlled lab

conditions. After hatching, individual larvae from each oothecum were transferred into separate petri dishes with either mint *Mentha* spp, gypsywort *Lycopus europeus* or hempnettle *Galeopsis tetrahit* to feed on. We recorded development time, pupae weight and survival. Pictures were taken of the adult beetles for morphological image analysis.

Preliminary data indicate differences in performance between and within populations. It seems that beetles from Skåne have a much lower probability of surviving on hempnettle compared to the populations in Halland and Närke. This difference between populations may be a result of adaptation to the local host plant community as the populations in Skåne do not contain hempnettle, while the population in Närke exclusively have hempnettle as host species, however the population in Halland neither contain hempnettle, only mint as host.

These findings can give us insight into local specialization patterns of phytophagous insects and how strength of selection from different host plant species varies among populations.

DNA methylation: a way for fast-renewed inbreeding depression in animals? An example with the mollusc species *Physa Acuta*.

Le Veve A¹, Cosseau C¹, Grunau C¹, David P²

¹IHPE, UMR5244, Univ Montpellier, CNRS, IFREMER, Univ Perpignan Via Domitia, ²CEFE, UMR5175

POSTER SESSION 2 - **P02.062**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Inbreeding depression (ID), defined as the reduction in fitness of offspring resulting from matings between related individuals compared to random individuals, has major effects expected on endangered species with small and/or declining populations, but also on evolution of the mating system. Usually, the main factor mentioned to explain ID is the loss of genetic diversity that compromise the evolutionary response to environmental change and the expression of recessive deleterious genetic mutations (named also genetic load) in inbred lines. However, this theory does not include an important factor that could also modify fitness of individuals, the epigenetic variants (or epi-alleles).

Despite the effects of DNA methylation and other epigenetic modifications on phenotypes, and the recurrent demonstrations of their contributions on rapid adaptation to environmental in different species, the potential negative effect of epigenome on individual fitness was not considered yet. Among all epigenetic marks, DNA methylation has received the most attention in evolutionary studies because of its pivotal role in repressing the mobilisation of transposable elements and gene expression, and of its potential inheritance. Moreover, DNA methylation variation arises at a considerably higher rate than genetic mutations in response to genetic, environmental and stochastic factors, creating fastly new advantageous or disadvantageous phenotypes.

Thus, epi-alleles, as genetic mutations, meet all the criteria required to promote ID in small populations: they can vary within and

between natural populations, be inherited across generations, and influence individual fitness. This assumption remains, however, to be tested in natural populations. Demonstrating the existence and understanding the evolution of this “epigenetic load” from an empirical point of view is essential to complete theoretically the expectations about ID in small populations.

Experimentally, to test this hypothesis requires distinguishing the contribution of the epigenetic to the overall ID by comparing the fitness of offspring from a series of controlled autogamous or allogamous crosses, but between individuals highly genetically inbred which deleterious genetic mutations were supposed highly purged.

Physa acuta is a short-generation hermaphrodite organism easy to breed in the laboratory, with a high level of ID in natural populations and that can self-fertilize when no partner is available. Using the progeny of the F1 obtained after crosses of two highly inbred lineages of this species, obtained after 28 generations of selfing, we demonstrated that fast new ID exist in offspring obtained by selfcross compared to cousin-cross. Then, using the phased haplotype of methylation obtained by Nanopore technology of grand-parents, parents and offsprings from the different type of crosses, cumulating with epiGBS data, we proposed an experimental protocol to estimate the component of ID attributed to the epi-alleles, their inheritance and identified this “epigenetic load”.

Drivers of adaptive evolution in a relict brown bear population

Colangelo P^{1,2}, Gramolini L¹

¹National Research Council, Research Institute on Terrestrial Ecosystems, ²NBFC - National Biodiversity Future Center,

POSTER SESSION 2 - **P02.098**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The evolutionary dynamics of small, isolated populations provide valuable insights into how genetic constraints interact with environmental factors to drive adaptive phenotypic shifts. The Apennine brown bear (*Ursus arctos marsicanus*), one of the most endangered, isolated and genetically depleted bear populations in Europe, exhibits striking phenotypic divergence from its conspecifics. Particularly, the rapid emergence of distinct cranial features, such as enlarged zygomatic arches and unique molar morphology, is likely associated with shifts toward a more herbivorous diet and may represent adaptive responses to the specific ecological context of the Apennines.

Here, we present the results of ten years of research on the evolution of this iconic relict population. This study provides valuable data on the mechanisms underlying phenotypic evolution in small, isolated populations.

Analyses of skull shape conducted on Apennine, Scandinavian, and Kamchatka brown bear populations using 3D geometric morphometrics suggested a reduction in morphological integration, i.e. the coordinated variation of traits due to genetic and epigenetic interactions, as a possible facilitator of increased phenotypic evolvability in the Apennine population. In particular, the altered trait covariance patterns in the in skull shape suggest that the relaxation of developmental constraints may have unlocked novel morphological trajectories. Hence, the observed differences of the Apennine brown bear may reflect adaptive evolution fostered by developmental plasticity rather than neutral processes alone. Although this population has recently been the subject of genomic studies, the molecular mechanisms underlying this divergence remain poorly understood. To gain additional insight into the microevolutionary processes acting at the population level, the potential role of epigenetic regulation in the evolution of this population was investigated by performing a

genome-wide methylation analysis on three European brown bear populations, Apennine, Alpine, and Scandinavian. Using Reduced Representation Bisulfite Sequencing (RRBS), population-specific epigenomic signatures were identified. The methylation profiles revealed marked population-level differences, highlighting epigenetic divergence as a potential driver of population differentiation. Around 50% of the differentially methylated regions (DMRs) were found both in promoters and non-coding areas distal from transcription start sites, suggesting that regulatory shifts, rather than single nucleotide mutations, may play a pivotal role. Gene Ontology analysis linked these DMRs to genes involved in anatomical structure development, morphogenesis, and immune function.

These epigenomic findings align with geometric morphometric analyses that reveal reduced morphological integration and increased fluctuating asymmetry, both considered hallmarks of altered developmental pathways. We propose that isolation and reduced genomic diversity, combined with epigenetically mediated regulatory changes, have contributed to the emergence of unique phenotypic traits in the Apennine brown bear. This case study may exemplify how developmental modifications, driven by changes in regulatory networks, can enhance phenotypic evolvability and promote adaptive divergence in small, isolated populations.

Our findings support an integrative evolutionary framework that combines epigenomics and morphometrics. This approach advances our understanding of how phenotypic novelties can emerge rapidly in small populations and underscores the importance of non-genetic mechanisms in shaping biodiversity. Such integrative insights are essential not only for evolutionary biology but also for informing the conservation of genetically impoverished yet phenotypically distinct lineages.

Ecological genetics of isolated loach populations indicate compromised adaptive potential

Wang X¹, Reid K¹, Chen Y¹, Dudgeon D¹, Merilä J^{1,2}

¹Area of Ecology and Biodiversity, School of Biological Sciences, The University of Hong Kong, ²Ecological Genetics Research Unit, Organismal and Evolutionary Biology Programme, University of Helsinki

POSTER SESSION 2 - **P02.075**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Many endangered species live in fragmented and isolated populations with low genetic variability, signs of inbreeding, and small effective population sizes - all features elevating their extinction risk. The flat-headed loach (*Oreonectes platycephalus*), a small noemacheilid fish, is widely across southern China, but only in the headwaters of hillstreams; as a result, they are spatially isolated from conspecific populations. We surveyed single nucleotide polymorphisms in 16 Hong Kong populations of *O. platycephalus* to determine whether loach populations from different streams were genetically isolated from each other, showed low levels of genetic diversity, signs of inbreeding, and had small contemporary effective population sizes. Estimates of average observed heterozygosity ($H_o = 0.0473$), average weighted nucleotide diversity ($\pi_w = 0.0546$) and contemporary effective population sizes ($N_e = 10.2 \sim 129.8$)

were very low, and several populations showed clear signs of inbreeding as judged from relatedness estimates. The degree of genetic differentiation among populations was very high (average $F_{st} = 0.668$), even over short geographic distances (<1.5 km), with clear patterns of isolation by distance. These results suggest that Hong Kong populations of *O. platycephalus* have experienced strong genetic drift and loss of genetic variability because sea-level rise after the last glaciation reduced connectedness among paleodrainages, isolating populations in headwaters. All this, together with the fact that the levels of genetic diversity and contemporary effective population sizes within *O. platycephalus* populations are lower than most other freshwater fishes, suggests that they face high local extinction risk and have limited capacity for future adaptation.

Effects of long-term inbreeding on assortative mating preferences and dynamic colour-ornament expression in a cichlid fish

Thünken T¹, Vitt S¹, Gussone L¹, Bakowski C¹, Douglas S¹, Okuducu U¹, Holtmann M¹

¹University of Bonn

POSTER SESSION 2 - **P02.067**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: The structuring of populations – due to natural or anthropogenic causes – can have important evolutionary implications. The resulting subpopulations are often small and prone to inbreeding. Inbreeding can lead to inbreeding depression, which severely affects fitness-related traits and can lead to population extinction. However, in combination with genetic drift, continuous inbreeding can lead to random genetic differences between subpopulations, which could contribute to population divergence and, thus, could drive diversification. In addition, purging processes associated with inbreeding can remove recessive deleterious alleles with large or medium effects from the population. Nevertheless, inbreeding depression may become apparent in polygenic, condition-dependent traits.

Methods: Here, we investigated the effects of long-term inbreeding on assortative mating and dynamic color expression during intra-sexual competition in *Pelvicachromis taeniatus*. This African cichlid fish shows intense biparental brood care and pronounced kin mating preferences. Both sexes display colourful ornaments that influence inter- and intra-sexual selection. Previous population genetic studies have shown that the natural population is inbred and substructured. Laboratory experiments revealed benefits from kin mating, as breeding pairs consisting of related individuals (full siblings) were more cooperative and less aggressive among each other than pairs consisting of unrelated individuals, as predicted by kin selection theory. Here, we conducted dichotomous mate choice experiments in which inbred and outbred individuals were given the choice between their own species vs. a foreign species, and kin vs. non-kin. Reinforced assortative mating preferences in

inbred groups could lead to divergent tendencies. In contrast, inbreeding depression could result in poorer performance of inbred fish compared to outbred fish. We also compared the effect of inbreeding on colour ornamentation in both sexes and the ability of inbred and outbred males to maintain intense body colouration during competition for breeding sites. Males show carotenoid-based yellow coloration in the fin and the ventral body region. Yellow intensity is condition-dependent and associated with dominance behaviour.

Results: Highly inbred individuals showed similar assortative mating preferences for the own species as outbred individuals. In terms of kin-mating preferences, outbred fish showed similar inbreeding preferences as in previous studies, whereas highly inbred fish preferred unrelated mating partners from a different inbred line to related partners suggesting that inbredness triggers outbreeding preferences. Inbreeding also affected the intensity of male colour ornaments with inbred males being less intensely coloured than outbred males after competing with rivals.

Conclusions: Our results indicate that persistent inbreeding does not reinforce assortative mating preferences and, thus, does not appear facilitate population divergence. In contrast, inbreeding induces disassortative preferences with respect to the genetic relatedness of the partner, i.e. highly inbred individuals showed inbreeding avoidance. This suggests an oscillation between inbreeding preference and inbreeding avoidance depending on the level of inbredness. Inbreeding depression in ornamental traits only became apparent in a competitive environment suggesting environment-dependent inbreeding depression.

Estimating realized relatedness in a wild baboon population and its implications for kin-biased behavior

Galán-Plana C¹, Rivas-González I¹, Ringbauer H², Archie E³, Alberts S^{4,5}, Tung J^{1,4,5,6}

POSTER SESSION 2 - P02.058, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Kinship is a major determinant of affiliative and mating behaviors in many animal species. While animals are often capable of discriminating between closely related individuals, the underlying mechanisms of kin discrimination typically remain unclear, especially in natural populations. This challenge stems in part from the problem that relatedness estimates based on pedigrees from natural populations are imperfect. Recent methods to infer the length and number of segments identical-by-descent (IBD) across the genomes of pairs of individuals can help overcome this problem, because IBD can be used to identify kin that are cryptic to observers, the animals themselves, or both. Here, we use genome-wide data from 433 wild baboons to estimate IBD-based realized relatedness within the intensively studied Amboseli population in Kenya. First, we demonstrate that IBD segments can be identified with high accuracy using genome resequencing data with as low as ~1x coverage paired with imputation. By using the resulting IBD calls, we both more precisely measure the actual

biological relatedness between known relatives (based on an independently constructed multigenerational pedigree) and identify new pedigree links that improve the match between pedigree and IBD-based relatedness estimates. In the process, we identified 17,396 cryptic relatives who were previously missed by the pedigree, but where IBD calls suggest third-degree relatedness or closer. Among these, 614 cases involve opposite-sex pairs of baboons who consorted as adults, and who were unlikely to identify each other as kin based on familiarity during development because they were born and matured in two different social groups. In 51 of these 614 cases, the pair produced inbred offspring. These results suggest that dispersal is a double-edged sword in our population—it frequently acts as a barrier to inbreeding by separating opposite-sex adult kin, but it sometimes introduces unfamiliar kin to one another in adulthood. Our findings thus lay important groundwork for understanding how and when kin discrimination in the context of mate choice evolves in the wild.

Evaluating genotype imputation in the Iberian lynx: a conservation genomics approach for small and endangered populations

Mayor-Fidalgo L^{1,2}, Bazzicalupo E¹, Pérez Sorribes L^{1,2}, Godoy J¹

¹Estación Biológica De Doñana, ²Universidad de Sevilla

POSTER SESSION 2 - **P02.101**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Small and isolated populations are particularly vulnerable to genetic erosion due to a reduced effective population size, increased drift, and inbreeding. The Iberian lynx (*Lynx pardinus*) experienced such severe bottlenecks that, by 2002, only ~100 individuals remained, and they were divided into two differentiated populations: Doñana and Sierra Morena. Thanks to several conservation actions, including captive breeding, translocations and reintroductions, populations are experiencing a remarkable recovery.

While high-coverage whole-genome sequencing (WGS) can provide valuable insights into evolutionary processes, it remains costly for large-scale studies. Low-coverage WGS (lcWGS) followed by genotype imputation offers a cost-effective alternative to characterize genome-wide variation in threatened species. Here, we assess the reliability of imputed genomic data for estimating key genetic parameters in the Iberian lynx, such as population structure, demographic history, and patterns of inbreeding and ancestry. **Materials and Method:** We downsampled high coverage (~25X) WGS data from 50 individuals of Iberian lynx to simulate lcWGS datasets at depths ranging from 0.1X to 2X. These individuals represented both remnant populations and admixed individuals and were used as a reference panel for imputation using GLIMPSEv1.1, following a leave-one-out validation approach. To assess scalability, we simulated a multi-target imputation scenario incorporating additional WGS data to be imputed from 150 individuals sequenced at ~1X, 19 at ~6X, and 11 at ~25X from previous studies.

Imputation accuracy was evaluated by comparing inferred genotypes under different quality filtering thresholds to those obtained from high-coverage data. We then reconstructed the demographic history of the species using

GONE, and estimated global (FROH, ADMIXTURE) and local genomic patterns of inbreeding and ancestry by analysing the overlap between runs of homozygosity (ROH) and ancestry-specific tracts in both high-coverage and imputed datasets.

Results: Imputation accuracy was generally high, increasing with coverage and varying among populations. The Doñana population, with lower genetic diversity and longer shared haplotypes, showed higher imputation accuracy overall, though heterozygous sites were less reliably recovered. The inclusion of additional samples in the multi-target imputation scenario significantly improved genotype concordance, particularly for the lower coverage datasets.

Global estimates of inbreeding and ancestry were largely consistent between high-coverage and imputed datasets. Nonetheless, local-scale patterns showed greater variation: longer ROH and recent ancestry tracts were recovered with higher accuracy than shorter segments which, in the case of ROH, were often overestimated. Similarly, GONE reliably inferred recent demographic events but produced less consistent results for older time periods.

Conclusions: Genotype imputation from lcWGS offers a reliable, scalable tool for evolutionary and conservation genomics in small and endangered populations. This strategy can recover reliable information on recent inbreeding, admixture, and demographic changes, particularly in populations with low genetic diversity. However, precision declines for older or finer-scale genomic features. Importantly, performing a multi-target imputation with as many WGS data available can significantly enhance imputation performance. For the Iberian lynx, this approach will be used to investigate recent evolutionary dynamics and informing ongoing conservation management.

Evolutionary dynamics of invasive *Vespula germanica*: The role of dispersal and climate in a restricted population

POSTER SESSION 2 - **P02.056**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Biological invasions drive rapid evolutionary change, challenging native biodiversity and ecosystem stability. They are a prime example of how populations founded by a few individuals expand and evolve in new environments. In South Africa, the European wasp *Vespula germanica* (Hymenoptera: Vespidae) established itself in the early 1970s and remains geographically constrained compared to other invaded world regions. This provides a unique opportunity to study the evolutionary dynamics of an isolated, slowly expanding population. We analyzed the genomes of 50 wasps representing the South African distribution using 2b-RAD sequencing. Our results revealed two main genetic clusters, each corresponding to a geographical region, which align with previously identified mitochondrial haplotypes and their distribution. This population structure supports the hypothesis of double

introduction and suggests limited male dispersal. Interestingly, the absence of isolation by distance patterns implies that gyne dispersal, whether natural or human-mediated, plays a significant role in maintaining genetic homogeneity within each cluster. Furthermore, we found an association between temperature and genetic structuring, with individuals from one cluster inhabiting warmer regions. This correlation, evident at both mitochondrial and nuclear levels, supports the hypothesis of climate-driven selective pressures shaping population structure and provides insights into the evolutionary processes occurring in small populations. This study represents the first genomic analysis of *V. germanica* and contributes to our understanding of population genomics and ecological dynamics in restricted populations of invasive wasps.

Evolutionary potential for pollutant tolerance in urban *Daphnia*

POSTER SESSION 2 - P02.084, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Due to a steady projected growth of cities in the near future and their associated stress and health risks for ecosystems and people, urbanisation has become a key aspect of global change. Urban ponds provide important ecosystem services in cities, but their functionality is threatened by influx of urbanisation-associated pollutants from different sources, such as urban stormwater runoff. Among these, synthetic organic chemicals - including those associated with traffic, such as tire wear chemicals - pose a growing threat to the ecological integrity of urban ponds. As urban ponds play a key role in mitigating climate impacts in cities, understanding how their biological communities respond to pollution is critical. Recently *Daphnia* have been used as a promising model system to study urban evolution. Their ability to top-down control phytoplankton blooms highlights their importance as key interactors in urban pond ecosystems. Urban stressors were previously shown to affect *Daphnia* fitness and species composition, potentially impacting their grazing capacities. Yet, little is known about how *D. magna* populations cope with increased pollution loads in urban ponds and whether populations differ in their

evolutionary potential to adapt to the emerging threat of urban pollution.

In this study, we exposed *D. magna* clones derived from 5 urban and 5 rural populations in the Berlin-Brandenburg area to the tire wear chemical 1,3-Diphenylguanidine (DPG). DPG is associated with traffic intensity and was recently shown to negatively affect another waterflea - *Moina macrocopa*. In a hierarchical design with clones nested in populations nested in level of urbanization, we analysed acute sensitivity of *D. magna* clones to evaluate to what extent there is genetic variation in tolerance within populations, whether populations differ in their tolerance and whether this is linked to urbanisation level. Our results point to substantial genetic variation in DPG tolerance across clones and populations, showing strong potential for evolutionary responses to changing pollution levels. Yet, we did not find an association between higher DPG tolerances and higher levels of urbanization, nor between DPG tolerance and measured DPG concentrations in the field. Nevertheless, our study provides insights into how rapid adaptation may shape future responses to anthropogenic environmental change.

Evolutionary rescue in small populations: latitudinal variation in wing polyphenism modifies genetic diversity and connectivity across natural populations in a water strider.

POSTER SESSION 2 - P02.079, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Species that occur in fragmented habitats and at small population sizes are at most risk of genetic erosion and local extinction, particularly during rapid environmental changes. Studying the evolutionary dynamics of small populations at both the phenotypic and genetic level is therefore of critical importance but remains difficult as these species are often rare and threatened. We use a natural study system of a species of water striders that occur in rivers and are widespread across Europe to examine how changes in an environmentally-induced phenotype (wing polyphenism) impact different evolutionary processes. *Aquarius najas* displays a latitudinal cline in wing frequency across Europe, with polymorphic populations in the South and wingless ones in the North. Hence, it represents an ideal system to study the interaction between a phenotypically plastic trait and how this alters genetic diversity and thus microevolutionary processes that impact survival of populations.

Materials and methods: To understand the population genetic consequences of wing polyphenism we first assembled a reference genome combining PacBio HiFi and Dovetail Omni-C with ISO-seq for annotation. To obtain estimates of genetic variation and differentiation we sampled multiple populations across Europe for sequencing (ddRAD/ low coverage WGS), focusing particularly on populations in Spain and Finland as they are located at the opposite ends of the latitudinal cline in wing frequency. We measured genetic diversity and inbreeding in each site, as well as differentiation between them. We reconstructed the demographic history of the species, obtaining both current and historical estimates of effective population size and we also reconstructed the species ecological niche at different timepoints to provide insights of the recolonisation of Europe after the Last Glacial Maximum and potential future response to climate change.

Results: The reference genome included 12 highly-contiguous chromosomes (L = 886Mbp, N = 73.5Mbp, 52% repeat content). Population genetic analyses for ca. 600 specimens revealed strong geographic clustering across Europe with 11 different lineages. These were mostly geographically restricted, although multiple coexisting lineages were detected in Spain and Finland. Country-specific structure analyses strongly suggest a higher connectivity across sites in Spain than in Finland, as expected given the higher frequency of winged individuals in Spain. These patterns are confirmed by measures of diversity, which are ca. 4-fold higher in Southern latitudes, as well as inbreeding and differentiation, which are low in Spain but extremely high ($F_{ST} > 0.65$ between sites ~20 km apart) in Finland. Measurements of effective population size indicate extremely fragmented populations in the North ($25 < N_e < 150$) and differ geographically.

Conclusions: Our study highlights the extreme fragmentation of natural populations of *Aquarius najas* and how a phenotypically plastic trait can dramatically alter fundamental evolutionary processes and the distribution of genetic variation. The species is subject to different evolutionary pressures with Southern populations exposed to great seasonal and yearly variability in their habitats due to a increased risk of habitats drying out because of climate change. In contrast, habitat stability of Northern populations is very high but populations are highly inbred and thus prone to genetic erosion as a result of low connectivity due to a lack of migrants. We demonstrate how important phenotypic plasticity can be in modulating dispersal and thus help determine microevolutionary patterns in a species that occur in a fragmented landscape at small population sizes.

Exploring the effects of first year cold-dormancy on the phenotypic, molecular and metabolic responses in head-started Gopher tortoises (*Gopherus polyphemus*)

Filipova A¹, Cochran C¹, Amer A¹, Goessling J², Shelton-Nix E³, Schwartz T¹

¹Auburn University, ²Eckerd College, ³Alabama Department of Conservation and Natural Resources

POSTER SESSION 2 - **P02.090**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Head-starting programs are increasingly used in reptile conservation to improve early survival by promoting expedited growth during early vulnerable juvenile stages. However, in species like the gopher tortoise (*Gopherus polyphemus*), endemic to the Southeast USA, the head-starting environment that promotes fast growth is often a dramatic shift from what those animals would be experiencing in the wild in their first year of life in its natural populations. Therefore, there is a significant gap in knowledge regarding how bypassing natural cold dormancy early in life impacts essential biological functions including growth trajectories, metabolic processes, and molecular responses in gopher tortoises that may impact fitness. In this study, we experimentally test the effects of bypassing first-year cold dormancy on growth rate, telomere length, mitochondrial DNA (mtDNA) density, and metabolic markers in head-started tortoises. We used a split-clutch design to assign 60 hatchlings from 14 clutches to two treatment groups: (1) a constant-warmth group raised under standard head-starting conditions without dormancy, and (2) a cold-dormancy group housed under simulated Alabama winter conditions. We took monthly body measurements and collected blood and plasma at four timepoints: before-dormancy (before), during-dormancy (during), 3 weeks post-dormancy (3Wk.Post) and 3 months post-dormancy (3Mo.Post). We estimated growth rate across timepoints, used qPCR to estimate mtDNA density and telomere length, and quantified glucose, total triglycerides and acetyl-CoA in blood plasma. We found that animals that experienced cold-dormancy were 8.47 mm smaller at 3Mo.Post dormancy relative to the constant-warmth group. This was due to the cold-dormancy group having a growth rate 0.54 g/day lower than the constant-warmth group during dormancy, and 0.51 g/day lower in the three weeks after coming out of dormancy (both results were

statistically significant). However, 3Mo.Post dormancy there was no statistically significant difference in growth rate between treatment groups. This indicates that although the cold-dormancy animals were smaller, they were able to resume the same growth rate as the constant-warmth group by 3Mo.Post dormancy but not the same body size. Additionally, there was no effect of either growth rate or treatment on telomere length across timepoints. However, while there was no difference in mtDNA density between the two treatment groups during dormancy, we found that the cold-dormancy group showed a significant 27.1% increase in mtDNA density at 3Wk.Post dormancy followed by a significant 17.1% decrease compared to the constant-warmth group 3 Mo.Post dormancy. Furthermore, during cold-dormancy tortoises had reduced plasma glucose compared to the constant-warmth treatment, but there were no differences at post-dormancy timepoints. Finally, our results showed that experiencing cold-dormancy caused a significant decrease in both total triglycerides and acetyl-CoA at 3Wk.Post dormancy compared to the constant-warmth. Total triglycerides at 3Mo.Post were not significant (acetyl-CoA was not measured). Our findings suggest that the period of growth and metabolic suppression associated with cold dormancy persists for at least 3 weeks after dormancy but is reversible by 3 months after dormancy. While telomere length might be maintained through compensatory cellular mechanisms during early life stage, the metabolic responses could influence energetic priorities and recovery processes associated with arousal from dormancy. These results have important implications for conservation management, suggesting that supporting the growth and metabolic health of reintroduced gopher tortoises may require greater attention to their natural physiological rhythms.

Exploring the Genomic Signatures of Convergent Dietary Specialization in the Adaptive Radiation of Canary Island Dysdera Spiders

POSTER SESSION 2 - P02.080, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Island radiations offer a powerful framework for investigating the molecular basis of evolutionary processes and evaluating their predictability. In archipelagos, the presence of multiple independent evolutionary replicates provides a unique opportunity to test for molecular parallelism underlying phenotypic convergence. Here, we study the remarkable diversification of the spider genus *Dysdera* in the oceanic archipelago of the Canary Islands, which has given rise to approximately 60 endemic species over the past 20 million years. This radiation has been accompanied by dietary shifts, including morphological, metabolic and behavioural specialisations for feeding on woodlice (Isopoda), which bioaccumulate exceptionally high concentrations of heavy metals from the soil. Hence, these endemic spiders represent an excellent model for investigating the evolutionary drivers and genomic factors underlying dietary convergence and adaptive radiations.

To understand the genomic basis of this specialization at short- and mid-term evolutionary timescales, we relied on a dual

approach integrating population and comparative genomic analyses. To this end, we generated high-quality chromosome-level genome-assemblies and performed low-coverage whole-genome resequencing of multiple individuals from natural populations of five endemic *Dysdera* species from the Canary Islands. The selected species were chosen to capture two independent shifts of dietary specialisation, each occurring in distinct evolutionary and geographic contexts. We uncovered exceptionally high levels of nucleotide diversity in all five species, indicative of large historical effective population sizes. In addition, we identified several candidate genomic regions that show signatures of recent selective sweeps, highlighting potential targets of adaptation. Furthermore, we are exploring whether changes in selective constraints are associated with dietary specialisation. This study advances our understanding of the genomic basis and the evolutionary forces shaping convergent evolution and adaptive radiation in island ecosystems.

First Insights into Population Structure of the Endangered Darwin's Fox (*Lycalopex fulvipes*).

POSTER SESSION 2 - **P02.077**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Darwin's fox (*Lycalopex fulvipes*) is currently the most endangered canid in South America, with less than 1,000 individuals surviving in the highly fragmented Valdivian temperate rainforest, an internationally recognized biodiversity hotspot in southern Chile. This small, forest-specialized endemic fox is threatened by deforestation and other anthropogenic activities, persisting in isolated native forest remnants. Despite its importance as a flagship species for the conservation of the Valdivian temperate rainforest, no population genetic studies have yet assessed the species across its full geographic range.

Materials and Methods: We reconstructed complete mitochondrial genomes for 37 Darwin's fox individuals spanning the species' current known geographic range, using mostly low-to-medium coverage whole-genome resequencing data (35 new, 2 previously published). This constitutes the first population-scale study of Darwin's fox using high-throughput sequencing. Phylogenetic relationships were reconstructed using median-joining, maximum likelihood, and Bayesian inference.

Results: We found differentiation between the two main distribution areas, Chiloé Island and the Chilean mainland, as well as further substructure among the latter. We observed a low number of haplotypes despite employing complete mitochondrial sequences, with high incidence of haplotype-sharing within localities, and high sequence divergence between geographic regions (incl. mainland localities).

Conclusions: This study addresses a major knowledge gap regarding intraspecific partitioning of genetic variation in Darwin's fox, providing the first insights into population structure and history of this endangered species. The observed distribution of intraspecific variation suggests restricted female-mediated gene flow among sampled localities. Additionally, molecular dating provides new information regarding the colonization of Chiloé Island by Darwin's foxes. These preliminary findings may be used to generate diagnostic mtDNA-variants for population assignment, thus benefiting evidence-based conservation planning.

From hives to genomes: inferring human impacts and genomic consequences of evolution in small bee populations

POSTER SESSION 2 - **P02.071**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Western honey bees (*Apis mellifera*) are essential pollinators, playing a key role in both biodiversity and agriculture. In Europe, traditional beekeeping - based on capturing wild swarms - has gradually been replaced by more modern practices, including raising queens, selecting high-performing lines, and using movable-frame hives. Although honey bees remain mostly wild, these changes explain why they are often considered a semi-domesticated species. After World War II, and especially since the 1980s, modern beekeeping has induced large-scale movement and mixing of honey bee subspecies. This has led to a reduction in the use of local subspecies (such as the black honey bee in Western Europe) and promoted artificial selection on others (e.g. *A. m. ligustica*, *A. m. carnica*, and Buckfast).

We analyzed hundreds of honey bee genomes to better understand their recent evolutionary history and how it affects current genetic diversity. Using Approximate Bayesian Computation, we found evidence of postglacial expansions and secondary contact between lineages before human influence. These natural processes were followed by more recent human-mediated movements.

To assess changes in population size over time, we used the program GONE. This revealed strong bottlenecks over the past 25 generations (~50 years) across many subspecies and breeds. Some exhibited gradual declines in GONE-inferred N_e which is likely due to selective breeding practices. These were especially strong in black honey

bee populations kept on small islands, where conservation programs have been set up to limit introgression from non-native bees. Indeed, these islands are often far enough from the mainland to prevent cross-mating, which helps preserve the native genetic background, but are limited in space and hive numbers. We analysed bees from two islands and inferred that both populations experienced a severe bottleneck when founded, and were maintained at very low effective population sizes ($N_e \sim 100$).

Among populations with low N_e values, we observed reduced genetic diversity, which may lower the bees' ability to adapt to environmental stress or disease, raising concerns about long-term sustainability of isolated conservation strategies. We also detected high levels of inbreeding and a moderate increase in the load of deleterious mutations, especially in regions of low recombination. This fits with the nearly neutral theory. The load is however likely limited by the fact that honey bees are haplodiploid, consequently recessive deleterious mutations in haploid males are more effectively removed from the population than in purely diploid systems.

Our study highlights that conservation programs, especially on islands, must consider genetic diversity and long-term viability. To achieve this, public funding for conservatories to facilitate genetic testing should increase, given their primary role in the preservation of genetic resources of one of the most important pollinators worldwide.

Genetic Diversity and Population Structure of Spanish Goat Breeds

POSTER SESSION 2 - P02.068, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Goats were domesticated around 10,000 years before present (YBP) in Southwest Asia and reached the Iberian Peninsula around 7000 YBP. Historically, goats were used to produce meat and milk and nowadays 22 caprine breeds have been officially recognized in Spain, of which 16 have a status of special protection to ensure their conservation. The main goal of the current work was to characterize the genetic diversity of Spanish goat breeds as well as to elucidate their population structure and genetic relationships using high throughput genotyping data.

Materials and methods: We collected either blood samples, DNA samples or Goat SNP50 BeadChip data from 19 Spanish goat breeds including Azpi Gorri, Blanca Andaluza, Blanca Celtibérica, Blanca de Rasquera, Bermeya, Cabra de las Mesetas, Cabra del Guadarrama, Eivissenca, Murciano-Granadina, Malagueña, Florida, Mallorquina, Moncaína, Negra Serrana, Palmera, Payoya, Pirenaica, Retinta, and Verata. Whenever required, genomic DNA was extracted from blood, and genotyping was performed with the Goat_IGGC_HTS_v3 BeadChip from Illumina which encompasses 79,538 single nucleotide polymorphism (SNP) markers. The PLINK software was used to filter out individuals and SNP markers. The final dataset included 457 Spanish goat samples and 41,626 variants. We also estimated the genomic inbreeding coefficient (FROH) as the proportion of runs of homozygosity (ROH) over the total length of autosomes using the R package “detectRun”.

Result: The Palmera breed had the lowest values of observed ($H_o = 0.288$) and expected ($H_e = 0.284$) heterozygosities, followed by the Balearic breeds Eivissenca ($H_o = 0.368$, $H_e = 0.382$) and Mallorquina ($H_o = 0.370$, $H_e = 0.377$). Performance of principal component analysis (PCA) of Spanish breeds revealed

one single cluster containing most Spanish breeds, that were weakly differentiated at the genetic level, with the only exception of Cabra del Guadarrama, that had a scattered distribution, and Palmera. This latter finding was anticipated because the Palmera breed probably originated from goats that were transported by Imazighen peoples to the Canary Islands approximately 2000 YBP. A second PCA excluding Palmera and Guadarrama evidenced a high differentiation of two Balearic breeds, Mallorquina and Eivissenca, and the Retinta breed that is mainly distributed in Southwest Spain. This result might be due to the insular origin of these two breeds as well as to their reduced population size, two factors that might have enhanced the impact of genetic drift on allele frequencies. We have also observed a south to north axis of diversity in the main cluster of Spanish breeds, with Northern Spanish breeds (Moncaína, Bermeya and Pirenaica) in one extreme and Southern Andalusian breeds (Murciano-Granadina, Malaguená and Florida) in the other one. Consistent results were obtained when analyzing genetic data with ADMIXTURE ($K=12$) The highest levels of inbreeding were found in Moncaína ($FROH = 0.096$) and Mallorquina ($FROH = 0.093$) breeds, likely due to their small population sizes. Indeed, the Moncaína breed was in danger of extinction at the beginning of the 21st century, with barely three hundred individuals.

Conclusions: Spanish goat breeds show high levels of genetic diversity and low FROH except for a few breeds that have undergone strong founder effects or population bottlenecks. The most differentiated breeds are Palmera, Guadarrama, Mallorquina, Eivissenca, Payoya and Blanca de Rasquera, while the remaining Spanish breeds are weakly differentiated.

Genetic surveillance reveals low, sustained malaria transmission with clonal replacement in Sao Tome and Principe

Chen Y¹, Ng P¹, Garcia D¹, Elliot A², Palmer B², Carvalho R³, Tseng L⁴, Lee C⁵, Tsai K^{4,6}, Greenhouse B², **Chang H¹**

¹Institute of Bioinformatics and Structural Biology, National Tsing Hua University, ²EPPIcenter Research Program, Division of HIV, Infectious Diseases and Global Medicine, Department of Medicine, University of California, San Francisco, ³Taiwanese Medical Mission, ⁴Taiwan Anti-Malarial Advisory Mission, ⁵Institute of Molecular and Cellular Biology, National Tsing Hua University, ⁶Institute of Environmental and Occupational Health Sciences, College of Public Health, National Taiwan University

POSTER SESSION 2 - P02.070, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Despite efforts to eliminate malaria in Sao Tome and Principe (STP), cases have recently increased. Understanding residual transmission structure is crucial for developing effective elimination strategies. This study collected surveillance data and generated amplicon sequencing data from 980 samples between 2010 and 2016 to examine the genetic structure of the parasite population. The mean multiplicity of infection (MOI) was 1.3, with 11% polyclonal infections, indicating low transmission intensity. Temporal trends of these genetic metrics did not align with incidence rates, suggesting that changes in genetic metrics may not straightforwardly reflect changes in transmission intensity, particularly in low transmission settings where genetic drift and

importation have a substantial impact. While 88% of samples were genetically linked, continuous turnover in genetic clusters and changes in drug-resistance haplotypes were observed. Principal component analysis revealed some STP samples were genetically similar to those from Central and West Africa, indicating possible importation. These findings highlight the need to prioritize several interventions such as targeted interventions against transmission hotspots, reactive case detection, and strategies to reduce the introduction of new parasites into this island nation as it approaches elimination. This study also serves as a case study for implementing genetic surveillance in a low transmission setting.

Genome Scans of Adaptive Introgression in the genomically eroded Iberian Lynx (*Lynx pardinus*)

Pérez Sorribes L¹, Lorenzo Fernández L¹, Mayor-Fidalgo L¹, Bazzicalupo E^{1,2}, Godoy J¹

¹Estación Biológica de Doñana (EBD-CSIC), ²Swedish Museum of Natural History

POSTER SESSION 2 - **P02.099**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: The Iberian lynx (*Lynx pardinus*) experienced a severe population collapse, reaching fewer than 100 individuals and placing it at the edge of extinction by 2002. Its demographic history, marked by low effective population sizes and serial bottlenecks, have resulted in exceptionally low levels of genomic diversity—among the lowest reported in mammals. Despite evidence for an overall loss of genetic diversity during the last decades, ancient DNA analyses revealed an increase in diversity in the last 4.000 years caused by introgression from the Eurasian lynx (*Lynx lynx*). Indeed, paleontological and genomic data supports extensive and recurrent, gene flow between both species, allowed by periods of range overlap in the Mediterranean basin since late Pleistocene and throughout Holocene. The fitness consequences of introgression remain unexplored, but an intriguing possibility is that introgression has restored functional diversity, resulting in adaptive introgression.

Material and methods: In this study, we perform genome-wide scans for adaptive introgression in *L. pardinus* using VolcanoFinder and high-coverage whole-genome sequencing data from 15 to 45 individuals. The top 1 % of VolcanoFinder outliers are taken as candidate regions and intersected with a newly developed *L. pardinus* genome annotation to identify

genes and gene functions potentially involved in ecologically relevant adaptations. Signals located within centromeric and telomeric regions have been excluded in order to reduce false positives. We then perform an over-representation analysis (ORA) on these gene sets to detect significantly enriched functional categories ($p < 0.05$). Finally, we assess the overlap between our candidate regions and those showing evidence of introgression (Bazzicalupo et al., in prep.) or positive selection (Lorenzo-Fernández et al., in prep.).

Results: This analysis revealed eight candidate regions of adaptive introgression distributed across five chromosomes. Within these regions, we identified a total of 337 genes and 1,748 associated Gene Ontology (GO) terms. The functional categories include immune and inflammatory response, tissue development and cell differentiation, lipid energy metabolism and neural functions.

Conclusions: This integrative analysis will contribute to a deeper understanding of the fitness consequences of introgression and the evolutionary mechanisms that have sustained adaptive evolution of *L. pardinus* despite its reduced genetic diversity.

Genomic consequences of recent population decline in the endangered butterfly *Hipparchia sbordonii*

Fava S, Kireta D, Gargano M, Gratton P, Cesaroni D, Iannucci A, Ciofi C, Gerdol M, Bertorelle G, Trucchi E

¹Univpm Ancona

POSTER SESSION 2 - **P02.104**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: *Hipparchia sbordonii* is an endangered butterfly endemic to the Pontine Islands, Tyrrhenian Sea, Italy. Understanding the genomic consequences of small and isolated populations is key to conservation genomics. We investigated genome-wide patterns of genetic diversity, genetic load, and demographic history in *H. sbordonii*, integrating data from historical (1990) and recent (2019) samples. As a comparative framework, we included the widespread congener *H. semele*, characterized by larger and more continuous populations.

Materials and Methods: Using whole-genome resequencing data from 28 individuals— ten *H. sbordonii* from Ponza (2019), three historical *H. sbordonii* from Ponza and three from Palmarola (1990), ten *H. semele* from the mainland (2019), and two outgroup species (*H. fagi* and *H. mersina*) — and a high-quality reference genome for *H. sbordonii*, we performed recent demographic reconstructions using GONE, estimated population genetic diversity (π , Tajima's *D*), inferred runs of homozygosity (ROH), and examined the functional impact of variants using SNPeff. This study is part of the ENDEMIXIT project (www.endemixit.com), which focuses on the population genomics of Italian endemic species.

Results: Genetic diversity (π) was substantially lower in *H. sbordonii* (mean $\pi = 3.579 \times 10^{-3}$) than in *H. semele* (mean $\pi = 6.525 \times 10^{-3}$), consistent with expectations for small populations. Demographic reconstructions based on recent samples revealed a marked decline in effective population size in *H. sbordonii* over the last

~30 generations, likely reflecting recent demographic contraction.

Tajima's *D* was near zero in historical samples of *H. sbordonii*, but showed a marked increase in recent samples, suggesting a signal of recent demographic contraction. In contrast, *H. semele* exhibited strongly negative Tajima's *D* values, consistent with population expansion.

To quantify genetic load, we used two outgroup species (*H. fagi* and *H. mersina*) to polarize derived alleles and calculated both masked and realized load per individual. Results revealed higher realized load in *H. sbordonii* compared with *H. semele*, consistent with reduced effective population size and increased inbreeding, as supported by a higher abundance and length of runs of homozygosity (ROH). Conversely, *H. semele* exhibited higher masked load, in line with its larger effective population size.

Interestingly, relative derived allele frequency comparisons (R'_{xy}) between *H. sbordonii* and *H. semele* showed a depletion of high-effect mutations in *H. sbordonii* (R'_{xy} High effect < 1), suggesting possible purging. However, moderate- and low-effect mutations were enriched (R'_{xy} Moderate effect > 1 , R'_{xy} Low effect > 1), potentially reflecting island-specific adaptations under relaxed purifying selection or directional selection in the insular environment.

Conclusions: Our findings illustrate the genomic consequences of recent decline and short-term small population size in *H. sbordonii*, with implications for its conservation. Ongoing habitat loss could exacerbate genetic erosion. Future work will include additional historical samples.

Genomic Insights into Anthropogenic Impacts on Small Mammal Populations Since the Natufian Period

Juravel K¹, Kahila Bar-Gal G^{1,2}

¹Koret School of Veterinary Medicine, The Robert H. Smith Faculty of Agricultural, Food & Environment, The Hebrew University of Jerusalem, ²Wildlife, CryoBank Collection, The National Natural History Collections at the Hebrew University of Jerusalem

*POSTER SESSION 2 - **P02.065**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM*

At the intersection of three continents, one of the world's most ecologically and culturally dynamic regions has served as a critical corridor for both human migration and faunal exchange since prehistoric times. This biodiversity hotspot, rich in endemic species and archaeological heritage, offers an opportunity to investigate how environmental and anthropogenic forces shape genomic diversity across millennia. Focusing on the Hula Valley ecosystem in Israel - once a vast wetland and now a landscape transformed by millennia of cultivation, drainage, and partial restoration (old times rewilding) we explore how repeated human interventions have affected the evolutionary trajectories of native mammal populations. Our study centers on small, vulnerable populations of the mountain gazelle (*Gazella gazella*), jungle cat (*Felis chaus*), and wildcat (*Felis silvestris*). We integrate genomic data from modern populations with historical samples (ca. 1960s) and ancient remains from the

Natufian period (~13,000 BP), including specimens from the Eynan (Ain Mallaha) archaeological site. Applying robust ancient DNA (aDNA) methods tailored to humid environments—from well-known protocols for aDNA extraction, in-house and commercial kits for dsDNA Library Prep for Illumina—we successfully recovered reads from genome-wide data from the degraded materials. Analyses of genetic diversity, demographic history, and population structure reveal pronounced temporal shifts linked to natural environmental changes and human land-use practices. These findings underscore the value of museomics and long-term population genomics in understanding how small populations adapt—or fail to adapt—under persistent anthropogenic pressure. Our work provides a critical evolutionary context for conservation planning and highlights the importance of integrating ancient and modern data to inform biodiversity resilience in an era of rapid ecological change.

Genomic Insights into the Evolution of Inbred Loach Populations: Phylogeny and Runs of Homozygosity

Hu S¹

¹Area of Ecology and Biodiversity, School of Biological Sciences, the University of Hong Kong

POSTER SESSION 2 - **P02.074**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

In nature, small, isolated populations often develop unique genetic characteristics. Such populations also experience reduced genetic diversity and increased homozygosity due to restricted gene flow and genetic drift, elevating their extinction risk and limiting their adaptive potential. Understanding the evolutionary dynamics of small, isolated populations is thus critical not only for unraveling the genetic consequences of demographic processes such as bottlenecks, inbreeding, and genetic drift, but also for addressing conservation strategies. While these patterns and processes have been extensively studied in laboratory populations and a handful of populations of iconic mammalian species, highly replicated studies of wild vertebrates remain rare. Therefore, the flat-headed loach (*Oreonectes platycephalus*), a small freshwater fish occurring in highly fragmented habitat, offers a valuable opportunity to study genetic consequences of isolation and small population size in highly replicated fashion.

Analysis of genome wide genetic diversity across 31 loach populations from southern

China was performed with the aid of whole genome re-sequencing data. Runs of Homozygosity (ROH) analysis indicated a predominance of short ROH segments (<100 kbp) in all populations, suggesting historical inbreeding. Inbreeding coefficients estimated from ROH (FROH) were particularly high in Hong Kong populations, averaging 0.37 and ranging dramatically from 0.11 to 0.72. Further analysis of ROH characteristics (total length and count) suggested that many of the populations have experienced population size bottlenecks and are consanguineous. To better understand their demographic history and evolutionary potential, we are now estimating their contemporary effective population sizes (N_e) and deleterious mutation loads, as well as evaluating to what degree the variation in these parameters are explainable by shared phylogenetic and demographic history. Our results so far suggest that many of the studied populations are likely to have severely reduced evolutionary potential and may suffer from increased load of deleterious mutations.

Genomics of caribou (*Rangifer tarandus*) in Western Canada: an assessment of inbreeding and demographic history

POSTER SESSION 2 - P02.085, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Conservation genomics plays a critical role in preventing population extinction by providing insights into genetic health and population dynamics. Inbreeding, a common consequence of small populations, reduces genetic diversity and increases extinction risks. Additionally, genetic drift further reduces effective population size (N_e) in small or isolated populations, exacerbating the loss of diversity. N_e is increasingly recognized as a key indicator for assessing genetic variation and the effects of genetic drift, particularly in vulnerable populations. In Western Canada, many caribou subpopulations are in decline or endangered, making the preservation of genetic diversity a priority under the federal Canadian Species at Risk Act (SARA). Increased predation and habitat degradation have led to smaller census sizes (N_c) and reduced connectivity between subpopulations, which limits gene flow. Specifically, several subpopulations have low census sizes, with some considered functionally extirpated and in decline of British Columbia. To identify at-risk subpopulations, we applied genomics tools to assess key indicators of genetic health. Using approximately 32,000 Single Nucleotide Polymorphisms (SNPs), we estimated inbreeding and contemporary and historical N_e for 45 subpopulations ($n = 759$) and 6 metapopulations across Western Canada. Inbreeding was assessed using Runs of Homozygosity (ROHs), and

N_e was estimated using LD-based methods implemented in the software 'currentNe' and 'GONE'. Our results show that smaller, more isolated subpopulations exhibit higher proportions of ROHs, indicating greater inbreeding. Shorter ROHs (<2 Mb) suggest historical inbreeding in all subpopulations, while longer ROHs (>8 Mb) are more common in smaller, endangered subpopulations. Notably, some subpopulations that were not previously known to be endangered showed high levels of inbreeding. Most subpopulations had low N_e estimates, with many falling below the critical threshold of 50, raising concerns for their short-term survival. Additionally, many subpopulations and all metapopulations had N_e estimates below 500, signaling risks for long-term viability. Contemporary N_e was generally smaller than N_c , and smaller subpopulations exhibited a higher N_e/N_c ratio. Historical trends in N_e show significant genetic bottlenecks in northern subpopulations between 1750–1850 and southern ones between 1900–1950, likely driven by climate change (end of Little Ice Age) and human activities before and after Euro-American settlement in Western Canada. Our study provides important insights into the genetic health and demographic trends of caribou in Western Canada, offering key indicators for active management, identifying sub populations 'at-risk', and implementing both short- and long-term conservation strategies.

Habitat-Driven Divergence: Early Development Variation in Two Ecotypes of the Marine Gastropod *Littorina fabalis*

Kumpitsch L¹, Sundberg H, Smirnov I, Neuman E, Metsmaa E, Haglund Morrissey N, Nyberg T, Karlsson K, Byh E, Garcia Guerrero D

¹University Of Gothenburg

POSTER SESSION 2 - **P02.103**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Small populations often face strong selective pressures, particularly in fragmented or ecologically contrasting habitats. The marine gastropod *Littorina fabalis* offers a powerful model for studying evolutionary divergence in such environments, as it comprises two ecotypes adapted to distinct microhabitats: a large-shelled form inhabiting moderately wave-exposed rocky shores, and a dwarf form restricted to sheltered areas. This species is distributed across the northeast Atlantic, and the present research was conducted on the Swedish west coast, where both ecotypes coexist among brown macroalgae, and the described ecotypes can be found. In this region, the ecotypes occasionally hybridize in contact zones, yet maintain striking phenotypic and genetic divergence. Genetic differentiation is particularly pronounced within 12 large, linked chromosomal inversions, which act as strong barriers to gene flow. While the ecotypes' differences in adult morphology and habitat preference are well documented, the potential role of early developmental traits in driving or reinforcing this divergence remains poorly understood.

In this study, we investigated whether microhabitat conditions shape early developmental traits in *L. fabalis* and whether these traits differ between ecotypes. We focused on the vulnerable phase from gastrulation to veliger stage, hypothesizing that each ecotype would perform better in its native habitat. We conducted two complementary experiments: a controlled temperature treatment in the laboratory (5°C, 10°C, 15°C, 20°C, 25°C) and a reciprocal transplant experiment between two field sites representing sheltered and exposed habitats. Egg masses from both ecotypes were collected and development time was tracked under stereo microscopy. Environmental parameters (temperature, salinity, oxygen) were

logged at each site to contextualize developmental differences.

Results showed that temperature had a clear effect on development: while little variation was seen between 10°C and 15°C, at 20°C the dwarf ecotype exhibited faster development compared to the large ecotype. However, in the field transplant experiment, the dwarf ecotype developed the slowest in both habitats. The large ecotype developed faster overall, and performed particularly well in its native exposed site, suggesting possible local adaptation. These findings highlight the complexity of environmental interactions in shaping life-history traits, particularly in small, partially isolated populations.

Both ecotypes showed a preference for laying egg masses on *Fucus vesiculosus*, regardless of habitat, suggesting that substrate availability or surface properties might also influence reproductive behavior. We also observed notable variation in egg mass morphology between ecotypes, as well as differences in microalgal colonization, particularly in the dwarf ecotype. These observations raise new questions about the potential functional significance of egg mass characteristics in buffering against microhabitat stressors such as temperature fluctuations or desiccation.

We are currently developing a developmental staging map for *L. fabalis* embryos and plan to combine proteomic analyses of egg masses with extended environmental monitoring. By integrating developmental, ecological, and molecular approaches, we aim to better understand how early life stages contribute to ecotype divergence in marine gastropods. Our work highlights how fine-scale environmental heterogeneity can drive evolutionary divergence, even in small coastal populations with limited dispersal.

Landscape driven isolation and inbreeding in specialist grassland butterflies

Nolen Z¹, van Riemsdijk I^{1,2}, Jamelska P¹, Torres Lara A^{1,3}, Rundlöf M¹, Wahlberg N¹, Runemark A¹

¹Lund University, ²Globe Institute, University of Copenhagen, ³University of Bremen

*POSTER SESSION 2 - **P02.107**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM*

Land use change from agricultural intensification has been highlighted as one of the major drivers of global declines in insects, reducing species diversity and abundance and shifting community composition towards generalist species. However, it remains a challenge to determine how land use change impacts the genetic diversity of species and populations even if this diversity is vital to their long-term persistence. Reductions in genetic diversity are expected to reduce adaptive potential and increase the frequency of deleterious mutations, potentially reinforcing demographic declines. We investigated to what extent grassland habitat loss associated with agricultural intensification in southern Sweden has resulted in genetic diversity declines in grassland butterflies from genomic data across multiple species to infer if differential demographic decline in generalists and specialists is mirrored by patterns of genetic erosion. Through a spatial comparison of populations of three grassland butterfly species, we uncover that specialist species show stronger genetic structure, with one specialist species, *Cyaniris semiargus*, experiencing sufficient isolation to lead to higher rates of recent inbreeding compared to the other species. Associating genetic diversity with land cover variables, we find that genetic diversity is lower in populations with less grassland area in the surrounding landscape due to higher rates of inbreeding. Comparisons between

genomes from contemporary and museum specimens of these same three species reveal the population isolation in this specialist species has arisen over the past century, increasing rates of inbreeding and reducing genetic diversity. Importantly, inbreeding has increased homozygosity of putative weakly deleterious mutations in this species, which may depress fitness of inbred individuals and reinforce decline. To determine if these patterns are general, we estimated the extent of genetic differentiation, reductions in effective population size, and recent inbreeding in Sweden's most common grassland butterflies and the European Grassland Butterfly Indicator species. While estimates of heterozygosity varied by species, rates of inbreeding were distinctly higher in specialists, as were levels of genetic differentiation between localities. Trajectories of contemporary effective population size over time reveal that while many widespread species maintain high effective population sizes, specialists have dropped to sizes below 500 and even 50 over the past 30-50 years. Together, these findings highlight that land use change has reduced functional connectivity and increased inbreeding in specialist grassland butterflies, and conservation efforts targeting habitat restorations that restore gene flow are necessary for the persistence of specialist grassland insect species.

Long-term genomic and morphological evolution of island vertebrates

Barcelo-Serra M¹, Bover P², Pons J¹, Valenzuela A¹

¹IMEDEA (CSIC-UIB), ²Instituto Universitario de Investigación en Ciencias Ambientales (IUCA)

POSTER SESSION 2 - P02.102, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Biodiversity can be defined across three hierarchical levels: ecosystem diversity, species diversity and genetic diversity. Among these, endemic species from small, isolated populations are of particular interest due to their unique evolutionary trajectories and increased vulnerability to environmental challenges. Islands, as biodiversity hot-spots, are characterized by a high number of endemic species and serve as natural laboratories for studying evolutionary processes in fragmented environments. Understanding the long-term dynamics of these populations is essential to assess species' adaptive capacities and resilience and to inform conservation biology managerial tactics. Technological advances now allow the study of morphological and genetic diversity in ancient populations, enabling the reconstruction of past demographic histories, the detection of genetic erosion, and the identification of early anthropogenic impacts. By integrating present-day genomics, paleogenomics and

morphological analyses, we aim to build a comprehensive view of how small populations respond to environmental pressures over time. In this work, we present an integrative study of two insular endemic vertebrates from the Balearic Islands: the reptile *Podarcis lilfordi* and the amphibian *Alytes muletensis*. Both species are characterized by small fragmented populations highly susceptible to genetic drift, inbreeding and environmental stress. By comparing ancient and modern mitochondrial genomes and morphological traits, we aim to quantify genetic erosion, assess microevolutionary changes linked to demographic fluctuations and human colonization events. Our approach provides a temporal perspective on the evolutionary dynamics of small, isolated populations, offering insights relevant for understanding resilience and vulnerability of insular endemic species in the face of ongoing anthropogenic pressures.

Loss of genetic variation and establishment of damaging variants in effectively small populations

Adepoju D¹, Ohlsson I¹, Klingström T¹, Rius-Vilarrasa E², Johansson A¹, **Johnsson M**¹

¹Department of Animal Biosciences, Swedish University Of Agricultural Sciences, ²Växa Sverige

*POSTER SESSION 2 - **P02.081**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM*

Domestic animal populations, as well as many animal populations in the wild, are effectively small and shrinking. In particular, in domestic animals with breeding programs, there is very strong directional selection, while breeds without modern breeding tend to be fragmented and in decline. Large-effect deleterious variants at relatively high frequencies are common enough in domestic animals that they pose applied problems for breeders. In our work, we have combined genomic data analysis with a

series of population genetic models to address the loss of genetic variation in effectively small and shrinking populations, and how large-effect deleterious variants establish themselves in small populations. The results suggest the presence of transient genetic variation, predicted to be gradually lost, and that balancing selection by heterozygote advantage, even transiently through close linkage, makes establishment of new large-effect deleterious alleles likely.

Mapping extinction risk in seahorses: integrating genomics, phylogeny, ecology and policy towards evolution-guided conservation

Bosso L², Biello R³, Olave M^{4,5}, Gabrielli M³, Stiller J⁶, Schneider R⁷, Benazzo A³, Bertorelle G³, **Raffini F**¹

³Department of Life Sciences and Biotechnology, University of Ferrara, ⁴Argentine Dryland Research Institute of the National Scientific and Technical Research Council, ⁵Faculty of Exact and Natural Sciences, National University of Cuyo, ⁶Villum Centre for Biodiversity Genomics, University of Copenhagen, ⁷Marine Evolutionary Biology, Zoological Institute, Kiel University

POSTER SESSION 2 - **P02.069**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Seahorses (*Hippocampus* spp.) are flagship animals with unique adaptations that inspire numerous conservation programs. They are the first marine genus to be fully listed on the Convention on International Trade in Endangered Species (CITES) Appendix II due to their substantial demographic decline, vulnerability to overexploitation, and habitat loss. The peculiar life history of these fishes has been widely addressed through evolutionary and ecological analyses. Yet, no study has integrated current knowledge to approach species-based conservation status, including trends in abundance, diversity, and threats, hindering seahorses' worldwide effective assessment and management.

Materials and methods: We bridge these gaps by taking advantage of the available geographic, ecological, and genomic (ultra-conserved elements and whole genomes) data in the *Hippocampus* species at a global scale and present the most comprehensive study of the seahorses' conservation status to date. We explore seahorses' diversity patterns in space and time by using species distribution modelling, phylogenomic mapping, comparative genomic applications, and conservation gap analyses. We consider their evolutionary history and genomic erosion, including genetic load, which have been largely disregarded by current conservation policies. We further assess the degree and type of protective measures currently

granted to seahorses and the biological and ecological factors that are contributing to their existing and future extinction risk.

Results: We showed that, despite being charismatic animals, their current level of protection is poor, particularly concerning their evolutionary diversity. We highlighted areas and species to be prioritized for urgent conservation interventions. Although genomic erosion appeared not to be an immediate concern in these species, most seahorses revealed a decline in their genome-wide diversity and an increased masked genetic load that may reduce their viability in the future. Our results raise questions on whether the current conservation indicators and practices are effective in preserving the present diversity and function of these iconic fishes, as well as their future evolutionary potential and ecological resilience.

Conclusions: These insights provide a unified, interdisciplinary perspective on seahorse conservation, emphasizing the need to integrate evolutionary history and genomic vulnerability into management policies. As "omics" and open-access data expand, we highlight unprecedented opportunities for research-driven conservation—ensuring these iconic fishes persist in the Anthropocene. Our framework serves as a model for assessing and protecting taxa of conservation concern worldwide.

Microevolutionary changes of *Daphnia galeata* during the oligotrophication of Lake Constance

Octorina P^{1,2}, Straile D¹

¹Limnologische Institut University of Konstanz, ²Universitas Muhammadiyah Sukabumi

POSTER SESSION 2 - **P02.082**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

This study investigates how *D. galeata* has adapted to environmental changes associated with the oligotrophication of Lake Constance, a deep, peralpine lake in Central Europe. Using a resurrection ecology approach, we established *Daphnia* clones from *Daphnia* resting eggs deposited in various sediment depths representing time periods with high nutrient concentrations (eutrophic: 1970 and 1980s) vs. low nutrient concentrations (oligotrophic: 1995 - 2015). We subsequently used two common-garden experiments to compare the performance of clones from the two time periods to a) the presence of predator kairomones and b) food availability.

Our predator kairomone experiment revealed that *Daphnia* from oligotrophic clones developed longer spines, but smaller heads and eyes regardless of predator presence, indicating microevolution of these body traits, but no evidence for evolution of phenotypic plasticity. The food availability experiment showed that under low food conditions, all clones plastically adjusted

their filter combs by increasing their size and setae length, but we found no differences between clones from the eutrophic versus the oligotrophic period. In contrast, the response of *Daphnia* life-histories traits differed between periods suggesting evolution of plasticity: *Daphnia* from the oligotrophic period showed later reproductive timings at low food concentrations compared to eutrophic clones.

These findings suggest that *D. galeata* showed a complex response to environmental changes associated with the oligotrophication of Lake Constance. This response included phenotypic plasticity, microevolution as well as evolution of plasticity of traits associated with food uptake, predator defense, and life history adjustments. We thus provide insights into how organisms integrate evolutionary and plastic responses to cope with environmental changes which likely will shift the relative importance of bottom-up versus top-down control for fitness.

Mitochondrial Divergence and Population Genomics in a Dwarf Insular Snake

Lindsey A¹, Sparkman A², Schwartz T¹

¹Auburn University, ²Westmont College

POSTER SESSION 2 - **P02.073**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Island ecosystems often host organisms distinct from their mainland counterparts in physiology, behavior, and morphology. A particular trend observed in both extinct and extant organisms on islands is a drastic increase or reduction in body size. The Channel Islands, off the coast of California, are home to several endemic species exhibiting reduced body sizes relative to the mainland; one of these is the Channel Islands gopher snake, *Pituophis catenifer pumulis*. We have been collecting morphological, physiological, and genetic data from two of the Channel Islands (Santa Cruz (SCI) and Santa Rosa (SRI)) along with northern (MN) and southern mainland (MS) California locations, and have demonstrated that island individuals are 30% smaller than their mainland counterparts, *Pituophis catenifer subsp.* The islands have experienced environmental degradation from human activity since the 19th century, but little is understood about the impact on endemic reptiles. These populations may experience dissimilar evolutionary forces compared to their mainland counterparts, with genetic drift likely playing a strong role in shaping diversity in neutral and functional genetic variation. Serpentes exhibit some of the highest mitochondrial substitution rates among vertebrates, and island populations across taxa frequently display significantly elevated non-synonymous to synonymous substitution rate ratios. This makes the mitochondrial genome particularly important for understanding the potential effects of genetic drift on functional divergence in isolated populations. By contrasting island and mainland populations, we can evaluate genetic diversity metrics, divergence between subspecies, and identify potentially functional mutations. Using whole genome sequencing data from 77 *P. catenifer* individuals across islands and mainland locations, we analyze demography at the level of

single-nucleotide polymorphisms (SNPs) from mitochondrial genomes. We found both islands contain their own unique mitochondrial haplogroups, with SCI containing two haplogroups and SRI containing one haplogroup. Haplotype maps indicate that at the mitochondrial level, island populations are more closely related to the southern mainland, which concurs with literature focused on only one mtDNA region. Pairwise genetic distances also show that SCI and MS are most closely related ($F_{st}=0.10$), and MS and MN are most distantly related ($F_{st}=0.89$). Interestingly, SCI exhibits higher nucleotide diversity compared to the mainland (SCI $\pi = 0.0049$, MS $\pi = 0.0016$). We also discovered several amino acid changes found in high frequencies on the islands relative to the mainland, a few that were private to one of the islands. On SCI, three of these five amino acid changes are clustered on NADH genes in Complex I and are found on the same haplotype. On SRI, four of these six amino acid changes are clustered on COX genes in Complex IV on the same haplotype. Whether due to selection or mutation accumulation due to drift, the non-random distribution of the amino acid changing haplotypes suggests the potential for functional consequences to mitochondrial performance that is being evaluated further. Presented results will include an expanded sample size that brings insight into a third island and a third mainland location, along with predictions of if island-unique mutations are functional. This research provides novel information about the population status and evolutionary history of *P. catenifer*, contributing to a broader understanding of how insular environments shape genomic divergence. Our data lays the groundwork for downstream functional genomics analyses to understand the genetic basis for the morphological and physiological differences between mainland and island populations.

Mutation bias influences adaptive evolution, even at large population sizes.

Barber J¹, Couce A¹

¹Universidad Politécnica De Madrid

POSTER SESSION 2 - **P02.055**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Introduction: Genetic mutation has long been seen as solely a stochastic force in adaptation. However, organisms can present with mutational biases, influencing which mutations arise at which positions, and evidence is showing an increasing role in dictating evolutionary pathways. Current consensus is that mutation biases can only play a prominent role in evolution when population sizes are small, and the power of selection is reduced. Understanding the scenarios in which mutation bias will play a critical role is necessary for predicting adaptive outcomes in natural environments and clinical settings.

Objective: To understand the role of population size in the predictive outcomes of mutator strain evolution to strong selection pressures.

Method: To address this, we evolve two *Escherichia coli* strains with distinct mutator alleles to doubling concentrations of the antibiotic cefotaxime, over a range of effective population sizes, and profiled the resistance alleles that fixed. Crucially, both

strains contain the beta-lactamase TEM-1, and only one mutator elevates first step mutations that increase cefotaximase activity.

Findings: We found a difference in survivability between the mutator strains, as well as increased survivability at larger population sizes. Furthermore, we found that whilst larger populations were able to find mutations associated with TEM-1, all populations still fixed resistance alleles associated with their mutation bias. Smaller sized populations showed mutational bias playing a dominant role, but interestingly each mutator strain responded to declining population sizes differently. We found extensive differences in resistances to other antibiotics as well, having implications for antibiotic combination treatments in clinical

Conclusion: This work shows that mutational biases can play an outsized role in evolution, and must be integrated into current evolutionary thinking in order to be able to anticipate evolutionary trajectories in adapting populations.

On the edge of extinction: genetic monitoring of the Aeolian wall lizard in a fragmented island system

Paris J^{1,2}, Berrilli E², Macale D³, Gambioli B^{4,5}, Carretero M^{6,7,8}, Ficetola G⁹, Bombi P⁵, Vignoli L⁴, Salvi D²

¹Department of Life and Environmental Sciences, Marche Polytechnic University, ²Department of Health, Life & Environmental Sciences, University of L'Aquila, ³Fondazione Bioparco di Roma, ⁴Department of Sciences, Roma Tre University, ⁵Institute of Research on Terrestrial Ecosystems, National Research Council, ⁶CIBIO Research Centre in Biodiversity and Genetic Resources, InBIO, Universidade do Porto, ⁷BIOPOLIS Program in Genomics, Biodiversity and Land Planning, CIBIO, ⁸Departamento de Biologia, Faculdade de Ciências, Universidade do Porto, ⁹Department of Environmental Science and Policy, University of Milan

POSTER SESSION 2 - P02.108, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The Critically Endangered Aeolian wall lizard (*Podarcis raffonei*) is an island endemic of the Aeolian Archipelago in Southern Italy. The species is currently recorded in only four locations: three tiny islets and the small peninsula of Capo Grosso on the island of Vulcano. With an estimated range of ~1.6 ha, a severely fragmented distribution, and a continuing decline in the number of mature individuals, urgent actions are necessary to monitor the genetic viability and conservation of the Aeolian wall lizard. An additional threat is competition and hypothesised widespread hybridisation with the introduced Italian wall lizard (*P. siculus*). In particular, the largest population of *P. raffonei* survives on a narrow peninsula (Capo Grosso) that is mildly connected to the island of Vulcano, which has been entirely invaded by *P. siculus*. Recent observations of individuals with intermediate phenotypes raised significant concern that hybridisation could swamp this last genetic stronghold. We genetically characterised lizards from Capo Grosso - including individuals with native, invasive, and intermediate phenotypes - and found a low hybridisation rate (~3%), with only

two F1 hybrids and two backcrosses. These results suggest that hybridisation is not currently a major concern in Capo Grosso. However, the population exhibits low genetic diversity, a small effective population size, and a low N_e/N_c ratio, while competition with *P. siculus* continues to pose a serious challenge to the species' persistence. As management strategies are urgently needed to control *P. siculus* and preserve the genetic diversity of *P. raffonei*, we initiated the LIFE EOLIZARD project, which includes a captive breeding program to address the species' decline and risk of extinction. We are undertaking a reintroduction of captive-bred *P. raffonei* individuals to two new islets, with the goal of establishing a sanctuary that will support the species' long-term conservation and serve as a safeguard for the species' genetic viability. To inform these efforts, we have performed a genomic screening for the selection of breeders to assess: 1) potential intraspecific hybrids; 2) genetic relatedness; 3) sex; and 4) genetic viability. Our future work will harness genetic monitoring methods to track the fitness of all introduced Aeolian wall lizards.

Patterns of inbreeding and purging selection in sand lizard populations in Sweden

Caroli L¹, Feiner N², Uller T¹

¹Lunds Universitet, ²Max Planck Institute

POSTER SESSION 2 - **P02.100**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sand lizards (*Lacerta agilis*) in Sweden have experienced a steep decline in the last decades due to loss of suitable habitat and fragmentation of originally connected populations. As the populations get smaller, there is increasing concern about inbreeding depression. Local extinctions have been widely documented especially in the northern range, where the populations are highly isolated; however, several populations have also shown a remarkable recovery following habitat restoration.

Using whole-genome data from 11 eleven locations covering the entire range of distribution, we determine the inbreeding status of the populations by analysing runs of homozygosity, as their length can be informative in dating the occurrence of consanguineous mating. Then we test the hypothesis that highly isolated small populations have a lower mutation load compared to larger more connected

populations. A stronger effect of purging selection in small, inbred populations has been reported in several other species but has rarely been studied in reptiles. We will verify whether the combination of increased inbreeding, which brings recessive variants in homozygosity, and purifying selection, which purges harmful mutations from the gene pool, is able to slow down the accumulation of deleterious variation.

Preliminary results confirm overall low levels of heterozygosity, with extremely high inbreeding coefficients in the northern range. This research, coupled with spatial analyses and forward simulations, will provide key insights for further work aimed at the conservation of this endangered species, for example, to identify: i) populations in critical need of management measures, ii) suitable populations for translocations, iii) effective strategies to improve connectivity.

Pleistocene climate and human impact shaped the demographic history of Mediterranean gray wolves (*Canis lupus*)

Sarabia C¹, Iglesias Santos F¹, Casillas Viladerrams S¹, Barbadilla Prados A¹

¹Universitat Autònoma de Barcelona (UAB)

POSTER SESSION 2 - **P02.083**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Climate change and human activity are among the most significant drivers of biodiversity loss, contributing to dramatic declines and local extinctions of wild species. Apex predators are particularly vulnerable due to their high energy requirements, small effective population sizes, and frequent targeting by humans—whether as hunting trophies or perceived threats. One of the most persecuted apex predators is the gray wolf (*Canis lupus*), a Palearctic species historically widespread across Eurasia and North America and well represented in the European fossil record since the Pleistocene. During the last centuries and due to human hunting, many gray wolf populations in Western and Southern Europe have undergone drastic declines, with widespread local extinctions and severe bottlenecks, particularly during the 20th century. In this study, we investigate how Pleistocene climate fluctuations and anthropogenic pressures shaped the

demographic history of gray wolves across the Mediterranean. We analyzed genomic data from 72 individuals representing three Mediterranean populations and inferred demographic changes using Markovian Coalescent-, Site Frequency Spectrum- and Linkage Disequilibrium-based approaches. Our results reveal a correlation between Pleistocene climatic events and fluctuations in effective population size. Additionally, we detect a negative association between wolf population size and human presence in several regions across the Holocene. Finally, we discovered strong genetic bottlenecks associated to systematic extermination campaigns carried out during the 20th century across multiple Mediterranean countries. Our findings highlight the long-term vulnerability of apex predators to both environmental and anthropogenic pressures and emphasize the importance of integrating genomic data and historical context in conservation strategies.

Population Genomics of Laboratory Zebrafish: Insights into Domestication and genetic diversity

Adrian-Kalchhauser I¹, Rajaraman S³, Ord J³, Jutfelt F²

¹University of Bern, ²University of Trondheim, ³University of Helsinki

POSTER SESSION 2 - P02.059, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Zebrafish (*Danio rerio*) are a central model in biomedical and developmental research, yet the population structure and domestication history of laboratory strains remain underexplored in an evolutionary context. Here, we present a comparative genomic analysis of five zebrafish strains—three sequenced in this study (TU, AB, JU) and two from public repositories (T5D, MA)—to investigate the genomic impact of domestication and inbreeding, with a particular focus on genetic diversity, population structure, and genes encoding epigenetic regulators.

Using shallow whole-genome resequencing of 95 individuals, we uncover substantial variation in genetic diversity between strains. Common laboratory strains such as TU and AB show extensive runs of homozygosity, consistent with inbreeding and genetic

bottlenecks, whereas wild-derived JU and MA retain higher heterozygosity. Demographic reconstruction via SMC++ suggests historical selective sweeps in all strains dating back ~1000 years, possibly linked to regional climatic shifts. Notably, genes under selection differ markedly between wild and domesticated strains, with a subset of loci consistently identified across domesticated lines, suggesting shared signatures of laboratory adaptation.

Our study enhances the resolution of zebrafish population genomics and provides essential context for future work in adaptation, selection, and domestication. The expanded individual-based genomic resource will serve the zebrafish community working at the interface of genetics and evolution.

Population genomics of the genus *Megasyllis* (Annelida, Syllidae) reveals hidden connectivity in the Canary Islands

Martín-Hervás M¹, RUIZ-LÓPEZ V¹, MORENO-MARTÍN P¹, Del Olmo I¹, Álvarez-Campos P¹

¹Universidad Autónoma De Madrid

POSTER SESSION 2 - **P02.089**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Syllid polychaetes are a group of marine annelids, inhabiting a wide range of oceanic environments worldwide. Despite their abundance and ecological importance, the population structure and genetic connectivity within the species of Syllidae family remains largely unexplored. In this study, we used a combination of genome-wide SNP data generated by RAD-seq and mitochondrial markers from multiple populations of a new species of *Megasyllis* sampled in 12 localities on four islands of the Canary archipelago (western Atlantic, Spain). Although the species was quite common across the different sampling sites in La Gomera and Tenerife islands, any specimen of *Megasyllis* sp. nov. was found on the easternmost islands of Fuerteventura and Lanzarote. Preliminary genetic analyses

in 83 individuals indicate high levels of gene flow among populations of the two sampled islands, suggesting a substantial connectivity of the studied species in this area. Moreover, we provide the first evidence of amphi-Atlantic genetic connectivity within the family Syllidae, with shared haplotypes detected among populations from the Canary Islands and Bermuda archipelago. These findings represent a novel biogeographic pattern for syllid polychaetes and underscore the potential role of long-distance dispersal mechanisms in shaping their population dynamics. Our results contribute to a more comprehensive understanding of the evolutionary processes influencing genetic diversity and connectivity in marine benthic invertebrates.

Purging and Accumulation of Genetic Load in an Expanding Population of Trinidadian Guppies

Burda K¹, Radwan J¹, **Konczal M¹**

¹Adam Mickiewicz University

POSTER SESSION 2 - **P02.076**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Genetic load refers to the presence of deleterious alleles in a genome that result in reduced fitness, often through homozygous genotypes. Demographic history can shape the genetic load of a population by influencing the efficacy of selection and levels of heterozygosity. Understanding these processes is essential for identifying threats to population viability and predicting evolutionary trajectories, especially in bottlenecked populations, such as those translocated by humans into non-native environments. These founder events may impact genetic load and shape a population's invasive potential. Here, we examine the causes and consequences of expansion in Trinidadian guppies (*Poecilia reticulata*) by estimating genetic load across the Turure River population, where translocated individuals rapidly spread and replaced native populations.

Materials and Methods: We sampled and sequenced whole genomes from 190 individuals across 14 populations in Trinidad and Tobago, including three populations along the Turure River. Samples were sequenced to an average coverage of 15×. Neutral genetic diversity was estimated at four-fold degenerate sites. Genetic load was assessed based on the presence of strongly deleterious loss-of-function (LOF) alleles, milder missense variants and using conservation scores (CS) of derived alleles.

Results: Genetic load was higher in populations from Tobago compared to

Trinidad and increased in upstream sites compared to downstream ones. These patterns were more pronounced for CS-based estimates than for LOF alleles. Consequently, we detected overall significant relationship between neutral genetic diversity and genetic load. However, in the Turure River, we observed contrasting patterns for LOF and CS-based estimates. Strongly deleterious LOF alleles were purged from the Turure population but tended to accumulate along the expansion gradient. In contrast, CS-based load was highest at the introduction site and declined downstream. Furthermore, we detected evidence of increasing admixture along the expansion gradient.

Conclusions: These patterns likely result from an initial population bottleneck and subsequent admixture with native populations. The founder effect led to the loss of deleterious alleles through drift and purging, while relaxed selection allowed mildly deleterious variants to accumulate. However, it appears that as a result of admixture from local populations, LOF alleles are being reintroduced to expanding population while mildly deleterious alleles are being masked. Together, our findings highlight how genetic load in invasive populations is shaped by population reduction followed by admixture, with important implications for understanding biological invasions.

Purging of highly deleterious mutations through an extreme bottleneck

Stuart O^{1,2}, Cleave R³, Pearce K³, Magrath M^{3,4}, Mikheyev S²

¹University College Cork, ²Australian National University, ³Zoos Victoria, ⁴University of Melbourne

POSTER SESSION 2 - **P02.078**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background. Transitions to captivity often produce population bottlenecks. On the one hand, bottlenecks increase inbreeding and decrease effective population size, thus increasing extinction risk. On the other hand, elevated homozygosity associated with inbreeding may purge deleterious mutations. Previous empirical studies of purging in captive breeding programs have focused on phenotypic measurements. We test natural selection's ability to purge deleterious mutations following an extreme population bottleneck by analysing patterns of genetic diversity in wild and captive-bred individuals of the Lord Howe Island stick insect, *Dryococelus australis*. *Dryococelus australis* has been bred in captivity for two decades, having passed through an extreme bottleneck—only two mating pairs with few new additions since then. The magnitude of the bottleneck together with high female fecundity but low offspring recruitment set up nearly ideal conditions for the purging of deleterious mutations, but the extremity of the bottleneck also suggests that this effect should be restricted to only the most highly deleterious ones.

Materials and methods. We generated low-coverage whole-genome sequence data of wild and captive *D. australis*, including individuals from a hybrid line which has ancestry from both the original captive breeding program's founders and a wild female collected recently. We estimated individual level heterozygosity and inbreeding as well as group-specific allele frequencies using a genotype-likelihood framework. Using the annotated genome

sequence for *D. australis*, we estimated the fitness effects of segregating mutations by their predicted impact on protein function and compared the frequency of mutations of different classes among wild and captive sample groups. We also sequenced one wild male to high coverage to assess the level of genetic diversity in the wild.

Results. Mean genome-wide diversity in the wild male sequenced to high-coverage was extremely low at $3.6e-4$. The chromosomal landscape of diversity was punctuated by long segments of near-zero heterozygosity indicative of recent inbreeding. Indeed, our estimate of FROH for runs-of-homozygosity > 1 Mb was 0.35. In the low-coverage data, captive-bred individuals had a greater number of long runs of homozygosity compared with wild individuals. Stop-codon mutations were preferentially depleted in captivity compared with other mutations in coding and noncoding regions. The more deleterious a mutation was predicted to be, the more likely it was found outside of runs-of-homozygosity.

Conclusions. Our results strongly support a role for purging of highly deleterious mutations in the landscape of genetic variation in captive *D. australis*, despite the extreme bottleneck and the relaxed selective environment of captivity. This provides a molecular context to the finding that purging may contribute to fitness change in captive bred populations with low N_e and underscores the role of deleterious recessive mutations in fitness variation in small, bottlenecked populations.

Range of trait variation in prey determines evolutionary contributions to predator growth rates

Hermann R¹, Pantel J², Réveillon T³, Becks L¹

¹University Of Konstanz, ²Université de Franche-Comté, ³INRAE

POSTER SESSION 2 - **P02.061**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Evolutionary and ecological dynamics can occur on similar timescales and thus influence each other. While it has been shown that the relative contribution of ecological and evolutionary change to population dynamics can vary, it still remains unknown what influences these differences. Here, we test whether prey populations with increased variation in their defence and competitiveness traits will have a stronger impact on evolution for predator growth rates. We controlled trait variation by pairing distinct clonal lineages of the green alga *Chlamydomonas reinhardtii* with known traits as prey with the rotifer *Brachionus calyciflorus* as predator and compared those results with a mechanistic model matching the empirical system. We measured the impact of evolution (shift in prey clonal frequency) and ecology (shift in prey population density) for predator growth rate

and its dependency on trait variation using an approach based on a 2-way ANOVA. Our experimental results indicated that higher trait variation, i.e., a greater distance in trait space, increased the relative contribution of prey evolution to predator growth rate over 3–4 predator generations, which was also observed in model simulations spanning longer time periods. In our model, we also observed clone-specific results, where a more competitive undefended prey resulted in a higher evolutionary contribution, independent of the trait distance. Our results suggest that trait combinations and total prey trait variation combine to influence the contribution of evolution to predator population dynamics, and that trait variation can be used to identify and better predict the role of eco-evolutionary dynamics in predator–prey systems.

Reframing the Himalaya: Genomic Insights from 1,217 individuals Into Migration, Isolation, and Malaria Adaptation in a Complex Human Landscape

Jha A¹, Penjueli M, Fahmy R, Gyawali A, Garcia O, Gautam Y, Bhandari D, Tandukar S, Gautam G, Sherchand J, Bustamante C, Ioannidis A

¹New York University Abu Dhabi

POSTER SESSION 2 – P02.066, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The Himalaya, the world's youngest and most dramatic mountain range, is often portrayed as a barrier to migration and a site of extreme ecological adaptation. Yet its broader demographic and adaptive history remains poorly understood. As a biogeographic crossroads and a mosaic of linguistic and cultural diversity, the region offers a rare opportunity to investigate how geography, culture, and deep population history intersect to shape patterns of human genetic variation. Here, we present a comprehensive genome-wide analysis of 1,268 individuals from 60 populations spanning the Himalayan arc—including remote and marginalized groups from Nepal, Bhutan, Tibet, and northeastern India—that expands the focus beyond high-altitude adaptation to encompass the full spectrum of ecological, linguistic, and sociopolitical diversity. By integrating newly generated genotype data with publicly available datasets, we implement local ancestry based tools to reconstruct population structure, admixture history, and patterns of genetic isolation across the Himalayan arc. We identify three distinct sources of East Asian ancestry, including a previously uncharacterized ancient lineage shared by Western Himalayan hunter-gatherers and indigenous Terai groups. South Asian

ancestry entered the Central Himalaya and Terai via at least two pulses—one predating the admixture that formed the ANI-ASI cline, and a second into the Kathmandu Valley. In contrast, Eastern Himalayan groups such as the Kiranti show little South Asian admixture, likely reflecting historical sociopolitical and geographic barriers. In addition, we uncover striking genetic isolation in small, nomadic, or geographically sequestered groups such as the Raute, Ban Rawat, and Toto exhibit extreme homozygosity and minimal gene flow, consistent with long-standing seclusion and endogamy. Beyond demography, we detect strong and replicable signals of local adaptation to malaria in lowland Terai populations, including selection at canonical genes such as AHSP, CR1, AFDN, THSD7B, and ANGPTL1. These findings underscore that infectious diseases—rather than altitude alone—have shaped genetic variation across the Himalayan belt. Taken together, our findings reframe the Himalaya as not just a static barrier and a site of ecological extremity, but as a dynamic frontier of migration, deep ancestral diversity and population continuity that has resulted in cultural complexity, and powerful localized adaptation.

Sexual selection and population spatial structure interact to shape sex-specific evolutionary responses in physiology

Iglesias Carrasco M¹, Tamburrino G², Lozano M³, Broggi J⁴, Garcia Gonzalez F³

¹University Of Copenhagen, ²University of Ferrara, ³Donana Biological Station, ⁴Museo Nacional de Ciencias Naturales

POSTER SESSION 2 - P02.095, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Sexual selection and sexual conflict may lead to sex-specific phenotypic expression of physiological traits because of the different selection pressures acting on females and males. We tested whether population spatial structure modulates the effect of sexual selection on male and female standard metabolic rates and oxidative stress. We used selection lines of the seed beetle *Callosobruchus maculatus* subjected to divergent evolutionary regimes in the intensity of sexual selection (high vs. low, in polygamous vs. enforced monogamous populations, respectively) and the presence of metapopulation structure (absent vs. present), and found that the evolutionary treatments impacted physiological traits in a complex way. In the selection regimes simulating metapopulation structure (i.e.,

divided populations) both sexes had similar metabolic rates; in undivided (unstructured) populations males had lower rates than females. Males from polygamous and undivided populations showed the lowest levels of antioxidant enzymes, resulting in strong sexual dimorphism in antioxidant capacity under this selection regime. The oxidative damage to lipids, instead, was highest for both males and females from monogamous and undivided populations. Our results reveal two key insights. First, physiological traits evolve differently in females and males in response to sexual selection intensity and population spatial structure. Second, such sex-specific physiological responses are linked to selective pressures acting mostly on males.

Speciation from Small Beginnings: Population Size and Environmental Heterogeneity Shape Speciation Dynamics in Individual-Based Simulations

Peacock C¹

¹University Of Manchester

POSTER SESSION 2 - **P02.097**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Understanding the dynamics and drivers surrounding speciation events remains a central goal in evolutionary biology. While classical theory proposes that large, geographically isolated populations are more likely to undergo speciation, which has been documented within real-world investigative studies, recent work which is largely based around simulation models has begun to challenge this view. Elements of alternative mechanisms of speciation, such as sympatry and parapatry, have proven difficult to investigate through conventional field or lab based methods. We utilise an individual-based evolutionary simulation software to investigate how parent species' population size and environmental heterogeneity affect the rates of speciation, community structure, and longevity of daughter species. Using the REvoSim simulation software, we analysed speciation events across multiple runs, with varying levels of environmental heterogeneity and rate of habitat change. Speciation was inferred from phylogenetic trees and speciation logs produced after the completion of each run. We quantified the population size of each parent species at the time of speciation and tracked the longevity

of the resulting daughter lineages, categorising environmental complexity using spatial heterogeneity metrics and rate of environmental change using habitat image refresh rates. Contrary to our expectations, we found that a large proportion of speciation events were skewed towards parent species with relatively small population sizes (less than 5,000 total individuals). These events often initiated rapid diversification clusters - bursts of daughter species emergence within narrow time windows. Further analysis found that the longevity of these clusters correlated positively with environmental heterogeneity, suggesting a stabilising role of more complex habitats. Preliminary spatial analyses suggest that many of these clusters do not align neatly with classical allopatric models, indicating potential parapatric or sympatric dynamics. These findings help to elucidate the role of parent species characteristics and habitat variability on the mode of speciation, providing insight into the mechanisms behind non-allopatric speciation events that are notoriously difficult to study.

Toads in Town: Conservation genetics of increasingly fragmented Western Leopard Toad populations in Urban Cape Town

Nelson H¹, Da Silva J^{2,3}, Leigh D^{1,4}

¹Senckenberg Nature Research, ²South African National Biodiversity Institute, ³Stellenbosch University,

⁴Goethe University Frankfurt

POSTER SESSION 2 - P02.092, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Understanding the evolutionary and selection dynamics of small, isolated populations in urban areas is crucial for developing effective conservation strategies. This is particularly important in cases where populations still have a viable chance of survival after small-scale conservation interventions. The Western Leopard Toad (*Sclerophrys pantherina*), an endangered species endemic to South Africa's Western Cape, is experiencing significant habitat loss as Cape Town's rapid urban expansion drives increasing human-wildlife conflicts. In this study, we use range-wide genetic data to assess species-wide population structure, connectivity, and gene flow within the species' contemporary landscape. Using 12 microsatellite loci genotyped across 84 individuals, we generated essential biodiversity variables (EBV), constructed spatial genetic networks, and applied estimated effective migration surfaces (EEMS) to investigate gene flow and movement dynamics in the species. Our analyses revealed strong population

structure, identifying three genetic clusters ($K = 3$) within the Western Cape—two of which were located within Cape Town—indicating restricted dispersal over relatively short distances. We identified potential 'genetic reservoir' sites exhibiting strong gene flow within remnant wetlands located at the boundary between urban development and natural habitat in central Cape Town. As well as a population at high risk of extirpation due to office block development. Temporal comparisons of genetic diversity from 2010 to 2021 showed no significant change in genetic diversity, suggesting a potential extinction debt driven by recent, rapid declines in key breeding sites that may not yet be reflected in genetic patterns. These findings highlight the role of human-driven selection in shaping urban species and highlight the importance of integrating genetic data into urban conservation planning to proactively mitigate genetic erosion and prevent vulnerable populations from needlessly reaching critical thresholds.

Topi or not topi: population structure of *Damaliscus lunatus* in Africa and its implication for conservation

Aninta S¹, Ciucani M¹, Bøggild T¹, Khan A¹, Schubert M¹, Martins N¹, Sinding M¹, Siegismund H¹, Moltke I¹, Albrechtsen A¹, Heller R¹

¹University of Copenhagen

POSTER SESSION 2 - **P02.096**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Africa is currently home to a high number of diverse megafaunas, and topi (*Damaliscus* spp.) is among them. Topi is a member of the Alcelaphinae subfamily of the Bovidae family. The IUCN Red List currently acknowledges topi taxonomy as a conservative arrangement of one species, *Damaliscus lunatus*, which is classified as Least Concern. Currently, topi is divided into six subspecies, *D. l. korrigum*, *D. l. lunatus*, *D. l. superstes*, *D. l. jimela*, *D. l. tiang*, and *D. l. topi* with no clear biogeographical barriers between these populations. Each subspecies is assessed separately by the IUCN with the *D. l. korrigum* and *D. l. tiang* assigned as Endangered, *D. l. jimela* as Vulnerable, and the remaining as Least Concern. There is yet to be genetic support for these assessments, which is substantial for managing taxa with trans-national distribution. We generated 71 whole genome sequencing data of *D. lunatus* populations collected from six countries across eastern Africa, representing populations from the native geographic distribution of *D. l. tiang*, *D. l. jimela*, *D. l. lunatus*, and *D. l. superstes*. Our preliminary results indicate that there were two major clades of *D. lunatus* representing southern topi (Botswana and Zambia) and eastern topi (Tanzania, Kenya,

Ethiopia, Uganda). Admixture analysis revealed a total of nine subpopulations with two coming from the southern area of their distribution. Investigation on their genome-wide variation showed that southern topi has relatively low heterozygosity, especially the ones in Uganda. The effective population size trajectory of the nine subpopulations also suggests that the samples' geographic origins likely represents the subspecies native to that region. Despite the distinct groupings supported by population structure, coalescence-based analysis, and genome-wide variation, gene flow has happened between geographically neighboring populations at a relatively moderate level. To understand whether the nine subpopulations represent distinct evolutionary significant units warrant separate managements, we are assessing their divergence time, genetic load, and conduct selection scans between subpopulations of more than ten individuals to detect local adaptation on separate putative subspecies. This work ultimately aims to elaborate the complexity of designating management units for taxonomically diverse mammals and how different alternatives would impact their long-term survival.

Turnover shapes evolution of birth and death rates

Kuosmanen T¹, Särkkä S², Mustonen V¹

¹University Of Helsinki, ²Aalto University

*POSTER SESSION 2 - **P02.057**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM*

A truly predictive evolutionary theory must be derived self-consistently from the underlying stochastic population dynamics, where the environment and ecology are not treated merely as confounders and mediators of evolutionary dynamics. By explicitly decomposing fitness to its birth and death components as well as accounting for how evolution and ecology respectively might affect them, we show how a fundamental asymmetry between reproduction and survival emerges. First, we derive a stochastic replicator equation from a general birth-death process and demonstrate the importance of the demographic turnover rate (defined as the sum of birth and death rates) on mutant fixation. Then we show how the

turnover rate shapes the distribution of evolutionary trajectories causing a systematic turnover bias in the mutant substitution dynamics in favour of less volatile low-turnover strategies. Finally, we provide theory for predicting how organismal growth strategies evolve in response to different population regulation mechanisms and show how the resulting life-history evolution has a clear direction where the pace of life becomes either slower or faster depending on the ecological context and mutational supply. Overall, our results highlight the importance of demographic turnover in evolution and underline the perils of quantifying fitness with a single parameter.

Understanding the social and genetic intergenerational impact of inbreeding depression in a wild population.

Pinto A¹, Lee K³, Gonzales S², Dong S², Dougdale H², Burke T³, Komdeur J², Richardson D¹

¹University Of East Anglia, ²University of Groningen, ³University of Sheffield

POSTER SESSION 2 - P02.093, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Understanding the full impact of inbreeding depression is key to informing effective conservation action. However, quantifying it can be complex in wild systems where recording accurate fitness measures and building accurate pedigrees over many generations is extremely difficult. As a result important aspects, such as the intergenerational cost to offspring of having inbred parents, are rarely considered and not fully understood.

Having inbred parents can depress the fitness outcomes of offspring (IID) for various reasons. Inbred social parents may be less able to provide resources and care for offspring, while inbred genetic parents can pass on damaged genetic material. The relative importance of these mechanism is difficult to disentangle. Fortunately, socially monogamous systems where extra pair paternity is frequent can allow us to separate the effect of an inbred genetic father from an inbred social father.

Here, we use exceptionally accurate lifetime fitness data, genomic inbreeding estimates and parentage assignments from >12 generations of a closed wild population of Seychelles warblers, where ca 40% of offspring are extra-pair. In this population IID

has already been identified through preliminary studies, but not well understood. We calculate inbreeding coefficients, we call runs of homozygosity in ~1900 imputed low coverage whole genome sequences. These data allow us to assess the level of IID and disentangle the relative effects of genetic vs social fathers on offspring fitness.

We predict that individuals with higher parental inbreeding coefficients will have shorter lifespans and produce less offspring due to IID. Furthermore, extra pair offspring will have different fitness outcomes depending on the inbreeding coefficients of their social and genetic fathers, thus allowing us to disentangle the relative importance of the mechanisms underpinning IID.

In this presentation I will outline our results and discuss their ramifications. As IID has rarely been examined in wild systems this study will highlight the relevance of finding the full impact of inbreeding. Having a full and nuanced understanding of inbreeding depression is important moving forward as we can only expect it to become more prevalent as populations shrink and fragment under intensifying anthropogenic conditions.

Unraveling the basis of adaptation to divergent habitats in chaffinch populations on the small island of La Palma

Fernández-Janoher M¹, Rancilhac L¹, Milá B¹

¹National Museum of Natural Sciences (MNCN-CSIC)

POSTER SESSION 2 - **P02.088**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Studying the evolutionary mechanisms that drive divergence and adaptation in natural populations provides valuable insights into the origin and maintenance of biodiversity and the functioning of biological systems. Oceanic islands, due to their unique characteristics such as limited size and geographical isolation, serve as optimal models for such research field. In this work, we analysed the phenotypic and genomic differentiation among populations of La Palma chaffinches (*Fringilla canariensis palmae*) inhabiting contrasting habitats: humid laurel forest and dry pine forest.

We statistically tested for differentiation in phenotypic traits measured in adult males, including weight, morphometric characteristics and plumage colour. We assessed genetic differentiation between habitats from 250 resequenced whole genomes (20x coverage) using PCA and genome scans of FST. We also conducted Genome–Environment Association (GEA) analyses to detect associations between genetic variation and two ecologically relevant habitat-related environmental variables. Lastly, we performed genome scans to detect signals of selective sweeps on both habitats to identify candidate genes under positive selection.

Our results highlight significant phenotypic differentiation in weight, morphology and plumage colouration across populations and habitat types. We found marked population structure in neutral markers despite the small geographic scale, indicating extremely restricted dispersal within the island. A redundancy analysis revealed clear habitat-related structure, with a separation between cloud and pine forest individuals along the first two RDA axes associated with vegetation greenness and temperature seasonality. Detection of multiple FST peaks of genetic divergence potentially associated to local adaptation and habitat-specific selective sweeps suggests polygenic adaptation. We characterized multiple loci in regions undergoing positive selection, which are involved in tissue development, body size, vision, and melanin pathways, among other functions.

In conclusion, we found evidence for the influence of strong genetic drift, due to small population size and reduced dispersal, a pattern commonly observed in populations colonizing oceanic islands. At the same time, we detected signals of divergence and positive selection associated with the two contrasting habitats, consistent with processes of local adaptation.

A natural experiment in brown trout *Salmo trutta* demonstrates the impact of demography on linked selection

Stuart O¹, McGinnity P^{1,2,3}, Reed T^{1,3}

¹University College Cork, ²Marine Institute, ³Environmental Research Institute

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Background. Within and among populations, patterns of genetic diversity are mediated by mutation, migration, drift, selection, and recombination. Recombination interacts with directional selection to reduce genomic diversity by linked selection. Linked selection removes haplotypes that carry deleterious mutations (background selection) or that do not carry beneficial ones (selective sweeps). There are positive correlations in locus-specific nucleotide diversity among closely related species, implying that conserved genomic features (such as conserved recombination rate heterogeneity) shape genetic variation via linked selection at long time scales. The efficacy of this should be modulated by demography, lower N_e populations being subject to greater genetic drift. Here, we test the hypothesis that demography modulates the strength of linked selection by exploiting differences in the degree of connectivity between recently diverged pairs of resident and anadromous populations of brown trout, *Salmo trutta*. Specifically, we hypothesise that (1) nucleotide diversity in 100 kb genomic windows should be positively correlated with local recombination rates in all populations, but (2) the strength of this correlation should be weaker in lower N_e closed resident populations. Additionally, (3) windowed nucleotide diversity should be less similar among pairs of closed resident populations than pairs of open anadromous populations due to the reduction in N_e .

Materials and methods. We generated low-coverage whole-genome sequence data from five resident-anadromous pairs of brown trout populations on the west coast of Ireland. Resident populations living above waterfalls that are impassable to upstream migrants are closed to immigration, whereas

anadromous ones below waterfalls in the same catchment are open. The independent isolation of these resident populations by the formation of waterfalls creates a natural experiment where different local genetic backgrounds are exposed to high (anadromous) and low (resident) N_e . We used a genotype likelihood framework to estimate windowed measures of genetic diversity and recombination rates in each population and compare these estimates across all pairs of populations.

Results. In all populations, there was a significant positive correlation between windowed nucleotide diversity and recombination rates. The slope of this positive relationship was greater for all anadromous populations than any resident population except for the Gweebarra resident population, which we suspect is not fully isolated from its anadromous counterpart. Correlations in windowed nucleotide diversity were greatest for anadromous pairs, weakest for resident pairs, and intermediate for resident-anadromous pairs, even when the resident-anadromous pair occupied the same river.

Conclusions. Overall, our predictions regarding the effects of linked selection were supported, demonstrating that a conserved recombination landscape at the intraspecific level governs the distribution of nucleotide diversity and that this relationship depends on demography. These results have implications for the study of parallel adaptation in divergent populations, as the overlap of responses to a shared selective pressure should depend on the overlap in the amount and kind of standing genetic variation, which in turn is affected by the interaction of recombination rates and demography. Our resident-anadromous population pairs make an excellent model system for these processes.

Adapting to a changing future: Is the 50/500 conservation rule adequate?

Nunney L¹

¹University Of California Riverside

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

Background: Global warming is a major threat to biodiversity that goes beyond recent precedent. Historically, many species survived environmental change by shifting their range, but now human-induced habitat loss and fragmentation commonly restricts range shifts, forcing species to adapt in situ or face extinction. While Haldane's "cost of natural selection" estimate, which limited the rate of adaptation to about one genetic substitution per 300 generations, is too conservative, this estimate took no account of any added constraint faced by small populations. These constraints can be examined through simulations that explicitly include environmental change, population dynamics and the frequency of adaptive mutations. Environmental change was assumed to continue for long enough to require novel adaptive mutations.

Materials and methods: Simulations of directional environmental change were performed using a model integrating population dynamics, mutation, the environmental fitness variance of genotypes, and selection. Genetic interactions ranged from additive (one trait) to multiplicative (several traits). The simulations examined the capacity of populations to adapt to an increasing rate of environmental change without going extinct. The model was applied in the conservation context of having either a single panmictic reserve or of a metapopulation of a linked set of smaller reserves. The metapopulation model examined the relationship between adaptation and the level of dispersal between adjacent sites.

Results: Persistence relied crucially on both carrying capacity and the rate of adaptive mutation. Although Haldane's estimate was found to be much too conservative except for the smallest populations, under most conditions a small population of several thousand or less was severely limited in its long-term response to rapid climate change, and vulnerable to extinction. When populations were subdivided, the simulations showed that metapopulations adapt similarly to a panmictic population if gene flow between neighboring reserves exceeds about two effective migrants per generation

Conclusions: Confronted by long-term directional environmental change, a general conclusion is that species unable to shift their range are vulnerable to extinction unless their population size is at least several thousand. However, while big is best, it also needs to be remembered that we cannot generally predict what adaptive challenges a given population may face. Even when a population is smaller than the ideal, any increase in size provides a significant increase in adaptive potential, and this may be enough to make the difference between survival and extinction. In fragmented landscapes, the only option for creating adequate adaptive units is by preserving metapopulations across a network of small reserves connected via habitat linkages. These results argue for significant investment in wildlife corridors, carefully designed to ensure effective function.

Ancient DNA rewrites the evolutionary history of the Western Palearctic robins

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

The extinct taxa provide crucial information on biodiversity loss. However, they can also illuminate us about ancient ecological interactions between extinct and extant species; changes in evolutionary history of migration; or how morphological traits can rapidly evolve. With the present study, we revealed several new extinct taxa found in the Atlantic oceanic archipelago of Azores. The cranial morphology of some of them was so different to any other species known that it deserved the common name of “Enigma”. We retrieved ancient DNA from some Enigma remains found in the island of Graciosa (Azores); and phylogenetic inferences unambiguously determine their phylogenetic positions. Both extinct taxa were grouped within the Muscicapidae family. One individual bone was strikingly grouped within the extant Canarian robin clade composed by *Erithacus superbis* and *E. marionae*. The

remaining bones sequenced were grouped in a new clade of its own. This new clade was sister to all Eurasian robins (*Erithacus* spp). The Enigma and the genus *Erithacus* shared a common ancestor 2.5-3.5 millions of years ago, and such age should be considered as the time of colonisation in Azores. Overall, our results show: 1) the arrival of robins and allied species in Azores, and Macaronesia, was the result of, at least, three independent bouts of colonisation in a relatively recent age (< 4 my); 2) in Azores co-occurred in sympatry two contemporary robin species plus a new morphologically distinct taxon named “Enigma”, however, only the extant European robin survived to human arrival; and 3) the unique morphology displayed by “Enigma” is likely a consequence of a rapid morphological change based on the age of divergence between the mitogenomes of the new taxon and modern robins.

Coping with insularity: genome-wide effects of isolation and genetic drift in highly diverse primates.

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

How do small, more isolated, populations of wide-spread genetically diverse species buffer against genetic diversity loss and genomic load? Insular populations persist at low population sizes, with lower levels of genetic diversity, and higher inbreeding than their mainland counterparts. Despite the potential for harmful genetic diversity loss, many populations remain stable and the genetic mechanisms that support this remain unclear. The spot-nosed monkey (*Cercopithecus petaurista*), the Campbell's monkey (*Cercopithecus campbelli*) and the green monkey (*Chlorocebus sabaeus*) are widespread and genetically diverse West African primates. Insular populations can be found at the Bijagós Archipelago, Guinea-Bissau. Here, we assessed the genetic diversity, inbreeding, genetic load and adaptive variation using whole genome sequencing data from insular and mainland

populations. In the three species, insular populations showed ~15 – 50% reduction in genome-wide diversity and ~70 – 90% higher proportion of the genome in ROH than mainland populations. Genetic drift has likely promoted the conversion of masked genetic load into realised load. However, we found no evidence for elevated deleterious variation in the insular populations nor increased rates purging. Species-specific traits, including high extant genetic diversity and ecological flexibility, likely support this phenomena. Despite their current stability, novel anthropogenic factors are increasingly threatening these insular populations and may interact negatively with the observed increase in realised load. Conservation management is advised to safeguard their remaining genetic diversity.

Developmental temperature, not inbreeding, shape life history and locomotor behaviors in juvenile guppies (*Poecilia reticulata*)

Hasan M¹, Jennions M^{1,2}, Head M¹

¹Australian National University, ²Stellenbosch Institute for Advanced Study (STIAS)

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

Environmental and genetic factors play a critical role in shaping life-history traits and behavior, yet their combined effects remain underexplored. Small, isolated populations are particularly susceptible to inbreeding, which can alter developmental trajectories and fitness-related traits. We examined how developmental temperature and inbreeding influence key life-history traits (early growth rate, size and age at maturity, survival, and sex ratio) and juvenile locomotor behaviors (boldness and habituation) in guppies (*Poecilia reticulata*). Guppies are live-bearing fish that typically inhabit shallow streams, which frequently fragment into isolated pools during the dry season, leading to inbreeding in natural populations. This makes them an ideal system to examine how environmental and genetic factors interact to shape life history and behavior traits in small population. Using a controlled breeding design, we generated inbred and outbred individuals that were reared at either a control temperature (26°C) or an elevated temperature (30°C) from birth until maturity. The developmental temperature strongly affected several life-history traits. Both sexes

matured earlier at 30°C, but only males exhibited slower early growth and reduced size at maturity, while female growth and size at maturity remained unaffected. Similarly, higher developmental temperature reduced the boldness of juveniles in both sexes; however, only females took longer to habituate to a novel environment. In contrast, inbreeding had no significant effects on any of the measured traits, nor did inbreeding interact with temperature. Our results indicate that, under our experimental conditions, developmental temperature was a driver of phenotypic plasticity in guppies, generating distinct sex-specific trade-offs in both life history and behavior. While inbreeding is expected to reduce fitness in small, isolated populations, our results suggest that its effects may not be universal and could vary depending on environmental conditions and the specific traits being measured. Such findings underscore the pivotal role of thermal and genetic environments in shaping developmental trajectories—an important factor to consider as the climate continues to change.

Dispersal evolution as a driver of island biodiversity

Van Wunnik S¹, Kauai Pereira F¹, Bonte D¹

¹UGhent

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

The origin of island biodiversity is thought to lie in the isolation that results from this peculiar geography. Several theories have been proposed to explain the underlying processes responsible for speciation, including dispersal theory. However, the role of dispersal in shaping patterns of biodiversity seems paradoxical: it induces speciation by providing individuals with new opportunities but inhibits speciation by allowing gene flow. We investigate whether this paradox can be resolved by considering dispersal as an evolving trait, given that dispersal is known to be under selective pressure. In addition, given a stable species richness in a system: is this the result of a low speciation rate or high speciation and

extinction rates balancing each other out? We test this using an individual-based model that mimics an archipelago system and compare this to a neutral landscape. We find that certain dispersal patterns are linked to specific island characteristics such as size and isolation, and prominent dispersal evolution is observed in approximately 10% of speciation events. However, dispersal evolution is not the sole driver of speciation: multiple speciation processes co-occur in the same landscape. Different mechanisms underlie the stable species richness for the different scenarios: speciation and extinction are rare in a heterogeneous landscape, whereas they cancel each other out in a neutral landscape.

Extreme climatic event causes genetic bottlenecks across a wild butterfly metapopulation: genomic consequences for population adaptative potential

van Dis N¹, Ruokolainen A¹, Nair A¹, Oostra V², **Saastamoinen M**¹

¹University of Helsinki, ²Queen Mary University of London

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Background: Climate change can exacerbate already poor habitat quality of small populations residing in fragmented landscapes. As many such populations will need to genetically adapt to persist, it is crucial to assess the drivers and constraints underlying their adaptive potential. We used temporal genomics to investigate the interplay between habitat fragmentation and climate change in a Finnish metapopulation of the Glanville fritillary butterfly (*Melitaea cinxia*).

Materials and methods: Utilizing a unique long-term sample collection from the last 15 years, we assessed how population fluctuations between years – resulting from the system’s inherent local extinctions and recolonizations dynamics – impact the effectiveness of selection in driving genetic change over time. To do so, we generated a high-resolution temporal genomics dataset, whole-genome sequencing 506 individuals from six replicate networks across 8 different timepoints, and used time-series and genotype-by-environment analysis to find adaptive genomic changes over time.

Results: Our time-series analysis showed that an extreme summer drought in 2018 not only resulted in a 10-fold decline in population sizes at the demographic level, but that this extreme climatic event also had severe genomic consequences in the form of genetic bottlenecks across the replicate sites. Effective population sizes across the networks were small (36-63 individuals) with strong drift resulting in genome-wide allele frequency changes over time. By combining genomic diversity and inbreeding measures with genotype-by-environment analysis, simulations, and a candidate gene approach, we discuss evidence for signatures of selection despite this strong drift.

Conclusions: Our genomic characterization of metapopulation eco-evolutionary dynamics highlights how an extreme climatic event can impact population adaptive potential, providing important insights into what determines the rate of genetic adaptation in small populations.

Fighting Through the Heat: How Sexual Selection Shapes Small Population Demography Under Recurrent Heatwaves

³School of Life Sciences, University of Essex

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

Sexual selection is a potent evolutionary force with complex effects. Strong sexual selection can enhance adaptation and reduce mutational load, while simultaneously reducing survival, or causing sexual conflict that reduces fitness for one or both sexes. Many populations today face not only gradual environmental changes but also extreme, short-term stress events like droughts or heatwaves. The combined effects of sexual and environmental selection on population demography during and after such events remain poorly understood, even though such combined effects could be crucial for the persistence of small, endangered populations under climate change. In this study, we investigated how sexual selection affects survival during environmental stress by manipulating the expression of an aggressive fighter morph in small populations of the male-dimorphic soil mite *Sancassania berlesei*, exposing some of these populations to recurrent periods of extreme heat and monitoring survival over eight generations. We found that heat exposure reduced survival, more severely in females

than in males, and survival was lower in populations with higher fighter prevalence, but there was no interaction between temperature and fighter morph prevalence. Furthermore, survival declined across generations, and the decline was steeper in populations with lower prevalence of fighters, leading to the loss of their initial survival advantage by the last generation. Three populations exposed to heat became extinct during the experiment, all from the reduced fighter expression treatment. Our findings imply that despite its cost to individual survival, sexual selection does not modulate population sensitivity to heatwaves over several generations. Furthermore, we demonstrate that these mortality costs of sexual selection are gradually compensated over successive generations, which could be a result of a more effective purging of inbreeding depression. Thus, while the additive effect of sexual selection and heatwaves on survival may increase demographic risks for small populations in the short term, sexual selection may increase resilience of populations to prolonged bottlenecks.

Genetic and dental variation: The effects of small population size in the endangered Saimaa ringed seal

Olkkonen E^{1,2}, Löytynoja A², Jernvall J¹, Kratochwil C^{1,2}

¹Institute of Biotechnology, Helsinki Institute of Life Science (HiLIFE), University of Helsinki, ²Faculty of Biological and Environmental Sciences, University of Helsinki

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Background: Genetic diversity is considered the raw material for natural selection and consequently for adaptation. Because genetic diversity is often higher in larger populations, it is widely assumed that larger populations also harbor more phenotypic variation in ecologically relevant traits and can better adapt to changes in their environment. Meanwhile, smaller populations might suffer from increased frequencies of maladaptive phenotypes. However, this hypothesis has limited support in wild populations. Here, we address the connection between population size, genetic diversity and variation in an ecologically important trait – tooth shape – using genomic and dental variation data from four ringed seal populations (Arctic Ocean, Baltic Sea, Lake Ladoga, Lake Saimaa) with greatly differing population sizes. The smallest of these populations is the endangered, land-locked and bottlenecked Saimaa ringed seal, with a census population size of less than 500 individuals, and the largest is the Arctic ringed seal population, with a vast geographic range and millions of individuals.

Materials and methods: We calculated nucleotide diversity (π) and derived allele frequencies using whole-genome sequencing (WGS) data from 86 ringed seal samples. We then measured dental diversity and the occurrence of tooth anomalies in the same populations. Specifically, we calculated the number of dental cusps for postcanines 2-5 in 150 seals per population and defined dental anomalies as the presence of enlarged or extra teeth. For the latter, we carried out genome-wide association (GWA) mapping using WGS data from 93 Saimaa ringed seals phenotyped for the anomaly.

Results: As hypothesized, our analyses showed both a higher average nucleotide diversity and a higher overall number of genetic variants, especially rare ones, in larger populations

compared to small ones. The average full-genome nucleotide diversity was 0.0031 for the Arctic population, 0.0029 for Baltic, 0.0027 for Ladoga and 0.0015 for Saimaa. Thus, nucleotide diversity varied by a factor of two between Lake Saimaa and the Arctic population. Allele frequency comparisons showed similar trends, with the number of singletons in the Arctic population (5822120) being an order of magnitude higher than in the Saimaa population (479051). Overall, the number of segregating biallelic SNPs in the Arctic population was three times that of the Saimaa population. Consistent with the genomic data, the phenotypic data support higher dental diversity in larger populations. The morphological disparity was 8.2 for the Arctic population, 7.4 for Baltic, 6.6 for Ladoga and 5.4 for Saimaa. Lack of rare morphotypes in the Saimaa population may be driven by a lower number or rare genetic variants or allele combinations, although adaptive changes due to a long isolation history may also be a factor. In contrast to the non-anomalous variation, we observed a higher frequency of anomalous dental variation in smaller populations compared to large ones (13.5% in Saimaa, 1.8% in the Arctic). Phenotype-genotype mapping revealed a ~140 kb wide candidate region associated with the phenotype. The region is located close to a gene essential for tooth development, *Bmpr1a*, and explains 4.2% of the phenotypic variation.

Conclusions: Our results support the theory of population genetics stating that larger, more genetically diverse populations also harbor more phenotypic variation in ecologically relevant traits, potentially indicating greater adaptive potential. However, anomalous dental variation with a suggested genetic component was more frequent in small populations, possibly due to the accumulation of these variants through reduced selection efficacy and increased genetic drift.

Investigating mutation load associated with adaptation in threespine stickleback

Nickel J¹, Laine J², Foote A¹

²Department of Natural History, NTNU University Museum, Norwegian University of Science and Technology

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Positive selection causes beneficial alleles to rapidly rise to high frequency in a population. This can cause linked genetic variation to “hitchhike”, and thereby also rise in frequency. This linked variation may include deleterious recessive alleles, previously neutrally harbored in heterozygous genotypes at low frequency. Modeling studies have shown that local effective population size and reduced recombination rate should contribute to the probability of deleterious mutations being swept to high frequency by being linked to beneficial alleles in selective sweeps or inversions. Sticklebacks provide an excellent system for understanding recurrent evolution. Marine sticklebacks have repeatedly adapted to thousands of freshwater habitats that became available after the last ice age, resulting in the formation of distinct marine and freshwater ecotypes. Upon colonization of new freshwater habitats, selection acts on ancient standing genetic variation present in

marine populations, causing freshwater-adaptive alleles to increase rapidly over tens of generations. These genomic regions play a key role in the repeated freshwater adaptation of morphological, physiological, and behavioral traits, and evolve under strong selection. We find that Norwegian lake populations with small effective population sizes share the core EDA haplotype containing freshwater-adaptive alleles. However, the flanking regions of this haplotype are highly differentiated between different lake populations, suggesting that different haplotypes have hitchhiked with the core EDA haplotype in each lake. We estimate the mutation load in regions of low recombination, including inversions, and the EDA haplotype. We find evidence for variation in hitchhiking mutation load among genomic regions and populations, suggesting a role for both local demographic history and genomic architecture. We highlight how this process could be more widespread in nature.

Phenotypic and genomic impacts of using inbred versus outbred rescuers in the experimental genetic rescue of small, inbred populations

Richardson D¹, West G¹, Nash W², Lewis R¹, Pointer M¹

¹University of East Anglia (UEA), ²Natural History Museum

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Anthropogenic change is causing many natural populations to become small and isolated, often leading to inbreeding depression. Genetic rescue aims to alleviate this problem by reintroducing genetic variation. However, the best source of such rescuers, and how that may impact the phenotypic and genomic consequences of genetic rescue, is not fully understood. For example, the traditional view recommends using individuals from a closely related, outbred population to rescue an inbred population. However, such outbred populations will likely harbour many deleterious alleles (masked genetic load), which will be introduced into the inbred populations. Such alleles may then become expressed in the recipient population in later generations if that population remains small. Therefore, it has been argued that using rescuers from closely related but different inbred populations, which should have purged more of their genetic load, may be better. We used *Tribolium castaneum* to experimentally test how productivity and

genomic characteristics differed in inbred populations rescued with individuals from different backgrounds. Our results show that outbred rescuers improved productivity the most, but rescuers from inbred populations still led to some degree of genetic rescue. In terms of the recipient population's genomic characteristics, outbred rescuers reduced inbreeding/RoH in the recipient population but inbred rescuers did not. Outbred rescuers did introduce more deleterious mutations, however, a greater proportion of deleterious alleles were in the heterozygous state in those population (i.e. the populations had lower expressed genetic load) than the populations rescued by inbred individuals. We also present results related to the use of rescuers from populations previously evolved under sexual selection versus monogamous regimes. Finally, we will discuss the importance of monitoring the downstream evolution of such rescued populations over many generations to fully understand the impact of the genetic rescue of small populations

Rapid vs. Slow Habitat Loss: Species Traits Shape Genetic Diversity Patterns During Contraction

Vishwakarma R¹, Maria Sgarlata G^{1,2}, Soriano--Paños D^{1,3}, Rasteiro R^{1,4}, Maié T^{1,5}, Paixão T¹, Tournebize R^{6,7}, Chikhi L^{1,6,8}

³Universitat Rovira i Virgili, ⁴University of Bristol, ⁵RWTH Aachen University, ⁶Université de Toulouse Midi-Pyrénées, ⁷Université de Montpellier, ⁸Faculdade de Ciências da Universidade de Lisboa

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Species ranges are dynamic, experiencing expansions, contractions, or shifts in response to habitat changes driven by climate change and human activities. Many species have recently experienced population decline, which, under a simplified theoretical model, is expected to reduce their genetic diversity over time. While some empirical studies support this prediction, others report that genetic diversity can be maintained or even increased despite a drastic decline. Here, we investigated how the dynamics of genetic diversity vary among species with different traits (such as generation length, population density, and dispersal) when subjected to a similar scenario of habitat expansion and contraction over millennia. Using both spatial simulations and a simpler panmictic population model, we investigated the temporal genetic diversity in refugium populations undergoing habitat expansion, followed by stationary and contraction periods. By varying habitat contraction speed

and species traits, we identified three temporal dynamics of genetic diversity during habitat loss: (i) a continuous decrease, (ii) a transient increase followed by a decrease, and (iii) a continuous increase. These different genetic diversity trajectories during habitat contraction help explain why rapid contractions did not consistently preserve more diversity than slower ones. More generally, we found varied effects of contraction speed on genetic diversity levels at the end of contraction. Specifically, we revealed a non-linear relationship: intermediate contraction speeds preserve greater genetic diversity than fast or slow contractions. This challenges the belief that high genetic diversity in a refugium population is due to a recent and rapid habitat loss. Overall, we demonstrate that genetic diversity patterns during habitat contraction depend on the interaction between species-specific traits and the dynamics of habitat change.

Recombination rate and efficiency of linked selection in small and large stickleback populations

Merilä J¹

¹The University of Hong Kong

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

Population genetic theory predicts that natural selection will be more efficient in large than small populations because genetic drift reduces efficiency of selection in small populations. Small populations adapting to new environments can also be expected to evolve higher recombination rates to facilitate adaptation as well as to dissociate and purge harmful mutations. We tested these hypotheses (1) by investigating differences in the strength of association between nucleotide diversity (π) and recombination rate across the genomes of nine-spined sticklebacks (*Pungitius pungitius*) from four small pond and four large marine populations, as well as (2) by comparing recombination rates between

small and large populations using population specific linkage maps. We found the predicted positive correlation of π with recombination rate from all but the smallest pond populations suggesting prevalent purifying selection even after accounting for variation in GC/CpG content, gene density, and mutation rate. Mean recombination rates were significantly higher in the pond than in the marine populations. These results suggest an important role for linked selection in reducing π in low recombination regions of both small and large populations. Moreover, as predicted by theory, pond populations appeared to have also evolved higher recombination rates than their marine ancestors.

Sky-Islands under pressure: how geography, climate, and genomic shape the history of an endemic Pyrenean species

Collette N¹, HINOUX V¹, PINEL S², Bertrand J¹

¹Laboratoire Génome et Développement des Plantes (LGDP), UMR 5096, Université de Perpignan Via Domitia (UPVD) - Centre National de la Recherche Scientifique (CNRS), ²Centre de Formation et de Recherche sur les Environnements Méditerranéens (CEFREM), UMR 5110, Université de Perpignan Via Domitia (UPVD) - Centre National de la Recherche Scientifique (CNRS)

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Understanding how small and spatially isolated populations respond to environmental change is a key challenge in evolutionary biology, with important implications for biodiversity conservation. High-mountain ecosystems, often fragmented into sky-islands, provide natural laboratories to explore these dynamics. Here, we focus on *Xatartia scabra*, a narrow endemic plant restricted to the eastern Pyrenees and the sole representative of a monotypic genus, to investigate how geography, demography, and environment have shaped its genetic structure.

Using a population genomics approach based on RAD-sequencing, we characterized genome-wide SNP variation across eleven populations sampled throughout the species' known range. Given the large genome size of *X. scabra*, RAD-seq provided an efficient and cost-effective alternative to whole-genome sequencing, enabling high-resolution insights into population structure and history. We combined these genomic data with species distribution modeling to reconstruct its geodemographic history and assess the role of past climate fluctuations in shaping current patterns of diversity and connectivity.

We found that genetic structure closely mirrors mountain summit distribution, supporting the hypothesis of persistent isolation among sky-island populations,

likely driven by topographic and ecological constraints. Despite this, traces of admixture between geographically neighboring populations suggest intermittent connectivity, possibly during past climatic optimum. These findings point to a complex demographic history involving both prolonged isolation and episodic gene flow. By integrating climatic variables, we further explore the potential for environment-driven genomic divergence. The association of some populations with temperature regimes and others with precipitation patterns suggests that environmental heterogeneity among isolated summits may contribute to genomic divergence through isolation-by-environment and possible local adaptation. Together, our results illustrate how long-term geographic isolation, demographic dynamics, and environmental heterogeneity jointly shaped the genomic landscape of this endemic species. By integrating population genomics with ecological modeling, we offer a comprehensive perspective on the geodemographic and genetic history of small, sky-island populations. It also raises important questions about the resilience of such taxa under future climate scenarios, emphasizing the need for conservation strategies that consider both patterns of genetic connectivity and environmental specificity.

Small populations and disease: Genomics of a severely bottlenecked species, the Critically Endangered Bellinger River Turtle (*Myuchelys georgesi*)

Nelson H^{1,2}, Farquharson K², Georges A³, DeGabriel J⁴, McLennan E², Giese M⁴, Belov K², Hogg C²

¹Senckenberg Nature Research, ²The University of Sydney, ³The University of Canberra, ⁴Department of Climate Change, Energy, the Environment and Water

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

Small, isolated populations are highly vulnerable to disease outbreaks due to genetic diversity loss. The Critically Endangered Bellinger River Turtle (*Myuchelys georgesi*) is a long-lived species endemic to a single river in eastern Australia, which suffered a severe population decline in 2015 following a novel disease outbreak. We conducted genome-wide and functional gene analyses to examine how small population size, genetic drift, and the 2015 population crash have influenced the contemporary genetic diversity of the species. To do this we generated a chromosome-level reference genome for *M. georgesi* and analysed 31 re-sequenced genomes to assess genome-wide and immunogenetic diversity within the major histocompatibility complex (MHC) from before ($N = 19$) and after ($N = 12$) the disease outbreak. We also undertook demographic history analyses to investigate temporal changes in effective population size. Genome-wide diversity in *M. georgesi* was critically low, with 90% of the genome within either a long or short run of homozygosity (ROH). However, the number of SNP variants within the functionally important MHC region

and across chromosome 10, exceeded that of all other macrochromosomes ($N = 9$). Additionally, we found the structure of the MHC core region to be highly conserved, a feature that has not been previously characterised in testudines. There were no significant shifts in genomic or MHC diversity from before and after the population crash, potentially due to genetic signatures of selection requiring multiple generations to show in this long-lived species. PSMC analyses revealed prolonged declines in effective population size, likely the result of historical bottlenecks associated with the species' isolated demography, which are reflected in the high prevalence of ROH. These genomic insights reveal how demographic events such as historical isolation and bottlenecks shape contemporary diversity patterns and may influence the adaptability of populations to anthropogenic threats, such as novel disease outbreaks. Additionally, our work highlights the growing importance of understanding genetics to support a multidisciplinary approach to conservation management and long-term viability of small, single-species populations.

Using proxies of genetic load to guide conservation management: do they deliver what they promise?

Robledo-ruiz D¹, Sunnucks P¹, Magrath M², Quin B³, Harley D², Pavlova A¹

¹Monash University, ²Zoos Victoria, ³Department of Energy, Environment & Climate Action

MEETING ROOM 115, August 19, 2025, 11:00 AM - 1:00 PM

A central question in conservation is how to manage threatened populations to improve their chances of long-term persistence. Small, genetically isolated populations risk extinction from inbreeding depression, loss of genetic variation and increased genetic load. The classic approach of minimizing inbreeding and increasing genetic diversity—by augmenting gene flow into genetically eroded populations—is effective at alleviating inbreeding depression and improving population fitness and growth. Recently, however, concerns arose about overlooking the effects of harmful genetic variation on fitness (i.e. genetic load). Because of the difficulty of measuring fitness in wild populations, methods that quantify genetic load focus on identifying putative deleterious variation, which is summarized into individual- and population-level measures. These proxies of genetic load are then used to infer the fitness of an individual (or population), and whether a population has undergone purging. One such method is GERP, which quantifies mutations' presumed harmfulness by identifying the level of evolutionary conservation of the loci in which they occurred. Despite the growing use of genetic load proxies to guide genetic management, the fundamental assumption that managing genetic load will lead to better conservation outcomes—because genetic load proxies are superior fitness predictors—has yet to be thoroughly tested. Here, we combined individual fitness and genomic data of the yellow-tufted honeyeater (*Lichenostomus melanops*) to test the key

assumption of genetic load studies of wild populations: that genetic load proxies predict individual fitness better than inbreeding metrics do. We reproduced 25 GERP-based individual genetic load proxies, and explored their association with lifetime reproductive success (LRS) of 43 wild birds. We also calculated inbreeding coefficients more typically used in genetic management: whole-genome homozygosity (FHOM), and Runs of Homozygosity (FROH). We found that although proxies of realised load predicted individual LRS to some degree, they were not the best predictors: the best inbreeding coefficient predicted LRS 21.1% better than the best genetic load proxy did. Additionally, total load proxies gave conflicting signals of whether *L. m. cassidix* experienced purging: four proxies indicated purging, three suggested accumulation of deleterious alleles, and five showed no differences. Our results suggest that caution is warranted when drawing conclusions about purging, until genetic load tools are validated and best practices are established. As more genomic data become available, more studies from wild populations with lifetime fitness data are needed to validate and benchmark different genetic load proxies. So far, there is no evidence to support the use of genetic load proxies instead of inbreeding coefficients to guide conservation programs. Wildlife management where load has been assumed to be the best predictor of fitness, or purging has been inferred, should be revisited in light of this growing evidence.

Variation among neighbouring wild populations of *Nicrophorus vespilloides* in mutation load and dependence on parental care

Dalehite W¹, Bladon E¹, Kilner R¹

¹University Of Cambridge Department Of Zoology

MEETING ROOM 115, August 19, 2025, 2:00 PM - 5:00 PM

Background: Although a substantial body of work has investigated the adaptive value of social behaviour, the contribution of social behaviour to local evolutionary processes remains underexplored. Yet this is key to understanding how quickly populations can adapt in a changing and fragmenting world. Previous research on lab populations of burying beetles (*Nicrophorus vespilloides*) revealed that post-hatching parental care can promote greater standing genetic variation and buffer against inbreeding depression. This means that, in principle, parental care can become evolutionarily self-reinforcing because it compensates for the negative effect of the increased mutation load it allows to build up. We investigated whether there is evidence to support this hypothesis using wild populations of *N. vespilloides*. We investigated whether six neighbouring wild populations vary in their resilience to inbreeding and in the extent to which larvae are dependent on parental care to survive.

Materials and Methods: Burying beetles provide elaborate biparental care for their larvae, which involves converting small vertebrate carrion into an edible nest for larvae, defending the nest and brood from attack and provisioning larvae with fluids through oral trophallaxis. Larvae are facultatively dependent on post-hatching care: they can survive without care in the lab though subsequently mature into lower quality adults. We investigated whether there is variation among six neighbouring wild populations, from ancient woodlands on the Cambridgeshire / Bedfordshire border, in the extent of larval dependence on parental care, and whether this is associated with mutation load (assessed by measuring inbreeding depression). Historical ecological analyses indicate that these distinct ancient woodlands are probably fragments of

the primeval Wild Wood that once covered most of England.

Each wild-caught population was bred in the lab in a common garden environment for at least three generations to eliminate any residual maternal and environmental effects. Each population was then split into four treatment groups: (1) Outbred with full care (control), (2) Outbred with no care, (3) Inbred with full care, and (4) Inbred with no care. To inbreed, we paired siblings. In the no care treatments, the parents were removed after preparation of the nest was complete but before any eggs hatched. Removing care in the inbred treatment allowed us to indirectly measure mutation load by observing inbreeding depression.

Results: Preliminary results indicate that these neighbouring wild populations vary in the degree of inbreeding depression, as assessed by comparing treatment (4) across populations. Furthermore, comparisons of treatments (1) and (2) across populations indicate that populations vary in the extent to which larvae are dependent on parental care to survive. Finally, comparisons of treatments (3) and (4) show that parental care buffers against inbreeding depression in all wild populations.

Conclusions: Even though these neighbouring wild populations of *N. vespilloides* are only between 1 and 10 km apart, they have apparently diverged in their dependence on post-hatching parental care and in their resilience to inbreeding. The challenge for future work is to test whether these factors are causally related, and to determine whether other factors might also affect mutation load - such as population size and heterospecific competition. This work will shed light on the ways social behaviour can influence the rate and direction of local evolution in a rapidly changing and fragmenting landscape.

Adaptive plasticity in escape behaviour: Crickets don't run as fast as they can when facing predator threat

Li R¹

¹University Of Exeter, Penryn Campus

POSTER SESSION 3 - **P03.034**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Predator-prey dynamics impose strong selective pressures on the evolution of anti-predator strategies, which constitute a fundamental adaptive response in wild animals. However, these strategies incur energetic costs, requiring trade-offs with other fitness-related traits. While predator-prey interactions have been extensively studied, empirical evidence for behavioural plasticity in responses across predation risk gradients remains limited.

We conducted field experiments on wild cricket (*Gryllus campestris*) nymphs in northern Spain, to investigate (1) how the intensity of predation cues influences escape speed adjustments and (2) whether anti-predator strategies vary by sex, developmental stage and according to

thermal conditions. We simulated two levels of vibrational cues: low-intensity and high-intensity. Contrary to our threat-sensitivity predictions, nymphs exhibited slower escape responses to high-intensity cues. This pattern may reflect ecological relevance: Low-intensity cues indicate immediate threats from avian or reptilian predators whereas high-intensity stimuli might resemble non-lethal disturbances from larger mammals or human activity.

Consistent with our previous findings in adults, escape speed in nymphs increased with body temperature. However, sex-dependent variation was observed only in adults, not in nymphs, suggesting developmental differences in anti-predator strategies.

Alpha and Beta Diversity of Cultural Traits in Global Jukebox Cantometrics Data

Nedomlel J¹, Storch D^{1,2}, Tureček P^{1,2}

¹Charles University, ²Center for Theoretical Study

*POSTER SESSION 3 - **P03.038**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

This study applies the ecological concepts of alpha and beta diversity to cultural traits. The goal is to explore how cultural traits vary within and between neighbouring groups of communities, and to evaluate the usefulness of these frameworks in studying cultural diversity. Alpha diversity metrics measures within-group variation, while beta diversity assesses differences between groups. As an example we use cultural data from the Global Jukebox dataset, a collection of traditional music along with cantometric song characteristics. Geographic and cultural patterns of diversity are investigated to reveal trends. The application of alpha and

beta diversity metrics demonstrates their potential as effective tools for analyzing cultural traits. These frameworks provide a structured way to quantify within-group variation and between-group differences, revealing patterns in the Global Jukebox dataset that align with expectations of cultural diversity studies. This study highlights the potential of applying ecological diversity concepts to cultural research offering a quantitative, scalable, and comparative approach to cultural variation and contributing to wider discussions on cultural evolution and diversity.

Arms-race dynamics drive rapid behavioural coevolution in a parasitoid fly and its host in Hawaii.

POSTER SESSION 3 - P03.032, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Host-parasite interactions are predicted to drive cycles of adaptation and counter-adaptation, but little is known about the genomics of behavioural co-evolution in animal systems. I will present work that identifies the genomic signature of behavioural coevolution during rapid arms-race dynamics in the wild in Hawaiian insects: an eavesdropping parasitoid fly (*Ormia ochracea*) attacks a field cricket (*Teleogryllus oceanicus*) that recently and adaptively lost its acoustic sexual signal. Across its native North American range, the fly uses a novel hearing organ to detect the sexual signals of crickets and katydids, but over the past 20 years, multiple male-silencing and song-reduction phenotypes have spread in Hawaiian *T. oceanicus*—convergent adaptive responses to escape parasitism. We identified genomic

signatures of counter-selection on flies imposed by rapid host defence evolution using ~350 fly whole-genome sequences and replicate field experiments. Using gene-environment association tests in which the fly's environment consisted of host adaptations present in each of 11 sampled Hawaiian focal populations, we found that strong selective sweeps in *O. ochracea* underlie rapid counter-adaptation to parasitise silent *T. oceanicus*. This occurred despite a strong population bottleneck following the fly's introduction into Hawai'i only ~50 years ago. Thus, sweeps are linked to local selection on the fly imposed by host adaptation to the fly itself. Our study reveals how genomic arms-race dynamics can drive rapid behavioural coevolution in natural host-parasite systems with prominent founder effects.

Comparing the sex-specific demographic history of primates with contrasting social systems

POSTER SESSION 3 - P03.051, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Non-human primates exhibit a wide variety of social systems, reflected in group composition, mating systems and dispersal behaviour. Depending on the social system, groups may exhibit unbalanced sex ratios or sex-biased reproductive skew. These social characteristics are expected to leave detectable genetic signatures, particularly on uniparentally inherited markers such as the Y chromosome and mitochondrial DNA (mtDNA), as well as on the X chromosome. For example, male-biased dispersal may increase Y-chromosome diversity within groups, while polygynous systems, where a limited number of males monopolize access to multiple females, are expected to reduce Y-chromosome genetic diversity relative to mtDNA genetic diversity. Although these genetic signatures have been highlighted in several species, the respective roles of group organisation, mating system and dispersal system in shaping uniparental and X-chromosome genetic diversity remain to be explored. Additionally, changes in social systems over time could also be traced through their genetic footprints. In humans, shifts in kinship systems towards patrilineal organisations following the Neolithic transition could have resulted in the observed reduction of Y chromosome diversity and male effective population size around 5000-3000 years ago.

In this study, we use a dataset of high-quality, whole-genome sequences from 19 primate species to investigate patterns of genetic diversity in uniparental markers, X chromosomes, and autosomes. We aim to assess whether these patterns correlate with known social systems, and whether shifts in these social systems can be identified through Bayesian inference of sex-specific demographic histories. One major challenge is the absence of assembled Y chromosomes in many primate reference genomes. To address this, we use a method based on differential coverage between females and males to identify and extract sequences from the Y chromosome, as well as from mtDNA, X chromosomes, and autosomes. This approach allows us to reliably genotype sex-specific markers even in the absence of fully resolved sex chromosomes, providing a robust dataset for demographic inference.

By comparing sex-specific demographic histories across species, we aim to increase our knowledge of the links between genetic patterns and group organisation, mating systems or dispersal strategies. Furthermore, our approach allows us to explore within-species variation and flexibility in social systems, and to detect potential historical transitions in these social systems.

Convergent patterns of visual adaptation in a community of mimetic butterflies

Wainwright B¹

¹University Of St Andrews

*POSTER SESSION 3 - **P03.043**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM*

Within complex tropical rainforests, niche partitioning can expose species to distinct sensory realms. For many animals, visual systems are the primary sensory conduit for interacting with the external world, but little is known of the role light variation plays in strengthening adaptive species assemblages and driving predictable patterns of visual system evolution within rainforests. By studying a community of 54 mimetic butterfly species from a diverse

Neotropical radiation, we take a comparative approach to demonstrate that rainforest architecture can create light microhabitats which drive sensory convergence towards distinct adaptive optima, at the perceptual and processing level. Our study offers a mechanistic insight into the evolvability of visual systems when confronted with similar ecological challenges and the wide-reaching indirect consequences of mutualistic mimicry on trait evolution.

Dissecting the genomics of migration in the Painted Lady butterfly

POSTER SESSION 3 - P03.046, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Insect migration is a multifaceted trait encompassing morphological, behavioural and physiological adaptations to environmental seasonality. While such complex traits are often underpinned by highly polygenic architectures with numerous variants distributed across the genome, some are shaped by discrete genomic regions with large effects. Insects exhibit a remarkable diversity in their movement types—ranging from full migration to sedentary lifestyles—which shapes connectivity and, ultimately, genetic diversity within species. This variation, apparent even within species, provides a valuable framework to investigate the genomic basis of migration. The migratory Painted Lady butterfly (*Vanessa cardui*) exemplifies this intraspecific diversity, exhibiting differences in migratory timing, orientation, and, in some populations, potential migratory loss.

In this study, we examine how migratory dynamics shape genetic variation across the nearly global distribution of *V. cardui*. By analysing 358 genomes, we test whether populations from two tropical island

archipelagos—Indonesia and Hawaii—have independently adapted to a sedentary lifestyle, a phenomenon known as "migratory drop-off." In contrast, we also investigate whether populations in the Northern and Southern Hemispheres have evolved distinct migratory strategies in the light of opposing seasonal regimes, a mechanism we term "hemisphericity."

Our results reveal widespread genomic signatures associated with migration loss in island populations, consistent with polygenic selection acting on numerous small-effect variants. Conversely, we uncover a 9 Mb chromosomal inversion differentiating mainland Northern and Southern hemisphere populations, pointing to a modular genomic architecture underpinning alternative migratory strategies at each hemisphere. Finally, we characterize genes and regulatory pathways linked to migration, including loci related to neuronal and hormonal regulation. Together, our findings illuminate the diversity of genetic architectures of insect migration and offer insight into the evolution of complex adaptive traits in natural populations.

Does it pay to be picky? How local adaptation in nesting behavior influences offspring phenotypes in a reptile with environmental sex determination.

POSTER SESSION 3 - P03.053, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The pervasive effects of developmental temperature on the embryos of ectotherms should pose a barrier to range expansion. This challenge is especially great for egg-laying species, which have little capacity to thermoregulate during development. Yet, a great number of oviparous ectotherms occupy broad geographic ranges. Local adaptation in nest site choice could allow parents to provide a suitable developmental environment for their offspring, yet evidence that oviposition site choice influences offspring phenotypes in an adaptive manner is rare. We investigated how geographic variation in the nesting behavior of *Chrysemys picta*, a widely distributed freshwater turtle with temperature-dependent sex determination, influences

offspring phenotypes. We compared predicted offspring sex and survival in maternally-selected nests to a random sample of potential nest sites in six localities across the United States. We found that maternal nesting behavior influences offspring sex; maternally selected sites were more likely to produce female offspring than randomly chosen sites. However, this effect was not always adaptive; in colder localities sex ratios were more biased in maternally selected sites than random sites, potentially indicating a trade-off between optimal sex allocation and offspring survival. Our results suggest that local adaptation in maternal nesting behavior facilitates range expansion in *C. picta*, but that the selective forces driving this behavior vary geographically.

Dynamic Genomes, Dynamic Behaviors: Multi-Omic Mapping of Predator-Induced Gene Regulatory Networks in *Daphnia magna*

Kiggen A¹, Van Belleghem S¹, De Meester L¹

¹KU Leuven

POSTER SESSION 3 - **P03.049**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Behavioural plasticity—the capacity of a single genotype to produce multiple phenotypes in response to environmental cues—is pivotal for survival in rapidly changing ecosystems. Yet, the gene regulatory networks that drive rapid behavioural shifts, the ways in which they vary among genotypes and phenotypes, and the processes by which these networks evolve under natural selection remain largely unresolved. Here, I outline an integrative research project using the freshwater microcrustacean *Daphnia magna*, which exhibits predator-induced shifts in behaviour, to illuminate these questions at three nested levels:

-The Gene Regulatory Network Behind Behavioural plasticity .

How are neural regulatory circuits reconfigured when individuals detect predator cues?

We will employ a combination of single-cell transcriptomic and chromatin-profiling techniques to capture the early and fully developed stages of the inducible antipredator response. By contrasting these molecular snapshots with behavioural assays, we aim to identify key regulatory factors and genes that switch the animal from one behavioural state to another.

- Genotype-dependent network variation.

How does standing genetic diversity shape the architecture and outputs of these networks?

A panel of *Daphnia* clones exhibiting a spectrum of predator-induced behavioural plasticity will be analysed under both control

and predator-cue conditions. Comparative network reconstruction will reveal whether variation among clones arises from differences in upstream regulatory factors, in the wiring of downstream effectors, or in the interactions between them.

- Evolutionary network change.

How do these gene regulatory networks evolve in wild populations facing different predation regimes?

Leveraging a genome-wide association study across natural clones from ponds across Belgium, we will pinpoint genomic regions—and ultimately specific variants—associated with behavioural responsiveness. Additionally, we aim to determine how selection acts on these genomic regions by comparing genotypes of populations with varying fish-predation pressures. Overlaying these findings onto our regulatory maps will clarify whether adaptation preferentially targets regulatory elements, coding regions of network hubs, or multiple loci in concert.

By forging a pipeline from cellular-resolution network dissection, through comparative genotype analysis, to population-genomic inference, this work aims to expose both the core, conserved modules and the flexible, lineage-specific adaptations that underpin predator-induced behavioural plasticity. The resulting candidate regulators, enhancers, and effector genes will lay the groundwork for targeted functional tests (e.g., gene knockdown or editing) and establish a generalizable framework for unraveling the evolution of complex behaviours in ecological contexts.

Evolutionary origin and maintenance of distinct song types that may promote reproductive isolation in the willow tit

POSTER SESSION 3 - P03.041, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Bird song is a culturally transmitted trait that can drive prezygotic reproductive isolation and speciation in songbirds. The willow tit (*Poecile montanus*) is a resident Palearctic songbird that shows striking geographic variation in song, with three distinct song types occurring mostly parapatrically across its range, separated by either sharp or gradual contact zones. One of these song types – the so-called “Alpine” song, a series of mono-frequency whistles – has a disjunct distribution, occurring in the alpine regions of Europe (Alps, Carpathians, Rhodopes) and in parts of East Asia (China, Kamchatka, Hokkaido), suggesting repeated gains or losses of song types during the evolutionary history of the species.

To gain insight into the evolutionary processes underlying this song type diversity, we sampled 93 individuals from across the willow tit’s distribution range, assembled a chromosome-level reference genome, and performed whole-genome resequencing for all individuals. Phylogenetic and population genomic analyses revealed five major genetic clusters: (1) Chinese, (2) Central Asian, (3) Central European, (4) Japanese (Honshu), and (5) a largely panmictic Northern

Palearctic group. However, these genetic clusters did not correspond to the distribution of song types; rather, the same song types were often shared across genetically distinct populations.

Demographic modeling suggests that all extant genetic groups originated in the early Pleistocene from an ancestral population in China that possessed the “Alpine” song type. As populations expanded northward and subsequently radiated westward and eastward across the Palearctic, a novel song type appears to have been gained, and one of the song types later lost in several isolated peripheral populations (e.g., Central Europe, Britain, Hokkaido, Kamchatka). Species distribution modeling and hindcasting support repeated cycles of range expansion and contraction into subdivided populations throughout the Quaternary, which would enable this scenario while maintaining relatively large effective population sizes.

Our results demonstrate how learned vocal traits can remain evolutionarily stable despite geographic isolation and may contribute to reproductive barriers in contemporary contact zones.

Facing hypoxia/reoxygenation stress in the nervous system of the Mediterranean mussel *Mytilus galloprovincialis*

Van Gelderen T¹, D'aniello E¹, Gallo A¹, D'aniello S¹, Carrella S¹, **Mirra S¹**

¹Department of Biology and Evolution of Marine Organisms (BEOM), Stazione Zoologica Anton Dohrn

POSTER SESSION 3 - **P03.039**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Intertidal organisms have successfully adapted to oxygen (O₂) fluctuations, due to both the intrinsic characteristics of the environment and the deoxygenation of aquatic habitats caused by eutrophication and warming. Facing hypoxia-reoxygenation (H/R) stress requires exquisite homeostatic responses, especially in tissues with a high metabolic demand, such as the nervous system. In hypoxia-sensitive organisms such as humans, neuronal mitochondria are the hub of H/R-induced neural damage, since O₂ deficiency impairs ATP production, whereas an excessive surge of O₂ causes a high production of toxic reactive species and consequently cellular damage. On the other hand, neurons of hypoxia-tolerant species are able to tolerate H/R, taking advantages of molecular tools evolutionarily tested to mitigate the damage associated with H/R.

Here we aim to dissect the cellular and molecular mechanisms underlying the natural resilience by which the neurons of hypoxia-tolerant mussel *M. galloprovincialis* tolerate H and H/R, with a particular focus on mitochondrial homeostasis. We set up a protocol to dissect neuronal ganglia from *M. galloprovincialis* and study them at morphological, cellular and molecular level. The morphology of ganglia has been observed by immunohistochemistry, showing their overall structure and the presence of the different neuronal types. Moreover, we are taking advantages from an experimental system to expose mussels to two different O₂ concentrations: normoxia

(N=7 mg/L O₂) and severe hypoxia (H<0,4 O₂). After 24 hours of H, a first cohort of animals is immediately sacrificed and dissected to obtain the ganglia (H condition). A second cohort is placed into a fully aerated aquarium for 1 hour to induce reoxygenation, prior to tissue isolation (H/R condition). Control animals are maintained in normoxia (N condition). The efficacy of the experimental protocol has been validated by quantifying the expression levels of Hypoxia-Inducible Factor (HIF-1 α) transcript in ganglia and gills (playing a pivotal role in gas exchange). Interestingly, HIF-1 α upregulation during hypoxia is induced at higher levels in gills than in ganglia, suggesting that specific or additional molecular pathways play a role in regulating neuronal adaptation under hypoxic conditions.

We will use molecular and cellular biology techniques, biochemical and computational analyses, imaging, and multi-omic (transcriptomic, miRNomic and proteomic) approaches to identify molecules and molecular pathways allowing neuronal functioning and surviving during extreme O₂ fluctuations. The latter has also a strong biomedical impact: H and H/R occur in medical conditions in humans, such as stroke. Therefore, novel data from hypoxia-tolerant mollusks will bring to light evolutionary adaptations that allow to prevent or mitigate the damage associated with H/R.

Functional adaptation and evolution of mandibular tusks in burrowing mayflies (Insecta: Ephemeroptera) explored via micro-CT and 3D morphometrics

Bae Y¹, Mayorga A¹, Lim C¹, Kim W¹, Shin S¹, Kang J¹

¹Korea University

POSTER SESSION 3 - **P03.037**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: The mayfly superfamily Ephemeroidea, commonly known as burrowing mayflies, is distinguished by the unique morphology and behavior of their mandibular tusks during the larval stage. These tusks resemble those of elephants or mammoths, yet unlike many exaggerated traits found in sexually dimorphic species, they occur in both male and female larvae and are absent in adults. In this study, we investigate the functional morphology and evolutionary trends of these mandibular tusks.

Materials and methods: We examined the functional morphology of mandibular tusks across all six tusked families of Ephemeroidea using 3D morphometrics based on micro-computed tomography, combined with an innovative automatic landmarking method employing point-cloud registration.

Results: Our findings quantitatively support and refine the hypothesis proposed by Bae and McCafferty (1995), demonstrating that mandibular tusk curvature and robustness are functionally linked to burrowing adaptations associated with substrate types in freshwater habitats. Principal component analysis of the mandibular tusks confirmed the differentiation of three dwelling morphotypes: interstitial, burrowing, and hard-substrate burrowing. Our 3D morphometric analysis—encompassing general tusk shape, curvature, center of

mass (CoM), and mass density distribution—further corroborated strong associations between tusk morphology and fossorial behavior. Evolutionary trends inferred from the current Ephemeroidea phylogeny suggest that interstitial dwellers with flattened bodies likely evolved early in the lineages of Potamanthidae and Euthyplociidae. In contrast, cylindrical-bodied burrowers, such as those in the basal lineages of Polymitarcyidae and Ephemeridae, as well as hard-substrate dwellers like Povilla–Ashenopus (Polymitarcyidae) and Cheirogenesia–Palingenia (Palingeniidae), appear to have evolved in parallel—each enhancing burrowing efficiency via modified forelegs. In addition, we report the discovery of a new species, *Drunella koreana* sp. nov., characterized by distinctive cephalic spines and belonging to a separate lineage, identified during our field investigations.

Conclusions: This study applied an integrated 3D morphometric approach to revisit the traditional hypothesis regarding the functional morphology of mandibular tusks in burrowing mayflies. Overall, our findings support the hypothesis proposed by Bae and McCafferty (1995), while extending current understanding of the tusks' functional adaptations. These structures exhibit sophisticated multifunctionality, playing key roles in substrate excavation, filter-feeding, and aggressive interactions.

Genetic and Environmental Drivers of Multiple Cognitive Abilities in Great Tits Living Along an Altitudinal Gradient

¹Station d'Ecologie Théorique et Expérimentale du CNRS, UAR 2029, ²Centre d'Ecologie Fonctionnelle et Evolutive, Univ Montpellier, CNRS, EPHE, IRD, ³ISEM: Institut des Sciences de l'Evolution de Montpellier ISEM, Univ Montpellier, CNRS, IRD, ⁴UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Université Montpellier, ⁵University of Toulouse, ⁶CRBE - Centre de Recherche sur la Biodiversité et l'Environnement, CNRS

POSTER SESSION 3 - P03.023, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Cognition is a key trait influencing how individuals respond to new environments, and it plays a central role in shaping selection and evolutionary responses. However, the relative contributions of genetic and environmental factors to variation in cognition have rarely been studied in wild populations, leaving a significant gap in our understanding of cognition's role in adaptation to environmental conditions.

To address this, we evaluated variation in cognition in wild great tits (*Parus major*) along an altitudinal gradient and assessed its genetic basis using a combination of quantitative genetic analyses and genome-wide association studies (GWAS). Wild-

caught great tits were tested in temporary captivity to reduce environmental noise and enable standardized cognitive testing. Specifically, we measured associative learning, reversal learning, problem-solving, and detour-reaching performance.

Our results show that cognitive abilities are repeatable, moderately heritable with a few SNPs explaining a percentage of heritable variation. The combination of quantitative genetics and genomic analyses suggests that cognitive traits are at least partially under genetic control. Overall, our study provides evidence that different cognitive abilities have the potential to evolve and points to a polygenic basis for these traits in great tits.

Identification of novel miRNAs in the deep-sea cephalopod *Pteroctopus tetracirrhus* with potential to rescue mitochondrial dysfunction in human diseases.

Van Gelderen T¹, De Vivo G¹, Crocetta F², D'aniello S¹, Mirra S¹, Carrella S¹

¹Department of Biology and Evolution of Marine Organisms (BEOM), Stazione Zoologica Anton Dohrn,

²Department of Integrative Marine Ecology (EMI), Stazione Zoologica Anton Dohrn

POSTER SESSION 3 - P03.040, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

In primary mitochondrial diseases (PMD) associated with severe neurodegenerative and retinal diseases, hypoxic conditions have been shown to partially rescue the phenotype by promoting a metabolic shift from oxidative phosphorylation to glycolysis. Therapies for PMD are limited and either invasive or symptom focused and new therapeutic strategies, such as those RNA-based, are being developed, offering a less distressing approach. Here, we aim to identify novel microRNAs (miRNA) from *Pteroctopus tetracirrhus*, a deep-sea cephalopod species naturally adapted to hypoxic environments, and test their potential to rescue mitochondrial phenotype in an in vitro model of PMD. To discover new miRNAs with potential therapeutic value, we extracted RNA from the retina of 3 individuals and performed small RNA sequencing. The genome of *P. tetracirrhus* is not currently available, thus, the genome of the closely related *Callistoctopus minor* was used for alignments. Mature miRNAs were identified using two independent tools, Prost and miRDeep2. Only the miRNAs detected by both tools in all three biological replicates were retained, resulting in identification of 92 mature miRNAs. Among these, 63 miRNAs showed conservation with known miRNAs in other metazoan species, while 29 were classified as novel. To narrow our focus to species-specific regulators, we selected 18

novel miRNAs that were not conserved with both *Octopus vulgaris* and *Homo sapiens* and had ≥ 10 normalized reads in each of the three samples. These miRNAs, named pte-miR-nov1 through pte-miR-nov18, were used to predict their functional target genes using miRanda and TargetScan, and only the transcripts identified by both algorithms were considered for downstream analysis. Gene Ontology (GO) enrichment analysis was performed on the putative targets of each miRNA to predict their potential biological roles. Four novel miRNAs—pte-miR-nov7, pte-miR-nov8, pte-miR-nov11, and pte-miR-nov14—were identified as strong candidates for rescuing the mitochondrial dysfunction phenotype. Each of them has the potential to target key glycolytic enzymes and genes involved in mitochondrial fusion and fission, or a potential role in modulating inflammation, which is commonly associated with mitochondrial dysfunction. Further analyses will allow us to determine the therapeutic potential of their modulation in a human in vitro model of PMD. Altogether, our work identified novel species-specific miRNAs with potential functional relevance to mitochondrial dysfunction in the hypoxia-adapted cephalopod *P. tetracirrhus* and will address their possible prospective as therapeutics in PMD.

Immunohistochemical mapping of diapause in the aphid brain

POSTER SESSION 3 - **P03.029**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

All organisms on Earth have evolved biological rhythms as an adaptation to face alternation of periods of favorable and unfavorable environmental conditions, at various temporal scales. Diapause is a state of seasonal dormancy, common in insects and other arthropods, that allows them to overcome recurring periods of adverse environmental conditions. Facultative diapause is triggered by biotic and abiotic factors that precede the arrival of the harsh season. The most prevalent signal that announces the arrival of the inimical season is day length (photoperiod). The capability of many different organisms to detect changes in photoperiod and produce a response is known as photoperiodism. Knowledge on the mechanisms that detect changes in photoperiod, and on the molecular, cellular and endocrine regulatory network that regulates the process in insects is scarce and fragmentary. Different studies have shown the involvement of the circadian clock machinery and of specific clock neurons, as well as of some neurohormones (e.g. insulin-like peptides) and neuropeptides. Aphids are hemimetabolous plant sap sucking insects that have been classically used as models to study photoperiodism. Their life cycles consist of several generations of viviparous parthenogenetic females followed by a single sexual generation, with males and oviparous sexual females. The sexual generation is induced by the shortening of photoperiod after the summer. The outcome of the sexual phase are cold resistant eggs that allow aphids to survive the winter. Thus, induction of the sexual phase is the way aphids enter diapause. Classical studies showed that the aphid brain is the center of photoperiod perception, signal integration

and elaboration of the adequate response that is transduced into the embryos instructing them to develop either as parthenogenetic individuals or as sexual morphs. Development of aphid specific antibodies allowed us to characterize cell groups in the aphid brain along with apparent connections between them, allowing the building of a putative map of the diapause in the aphid brain. These included distinct types of neurosecretory and clock cells located in key brain regions, such as the dorsal and lateral protocerebrum, and also in the lamina. Some of these neurons co-express circadian proteins, such as PERIOD (PER) and the photoreceptor CRYPTOCHROME 1 (CRY1), putatively involved in photoperiod sensing. Their projections toward neuroendocrine centers suggest direct communication between the circadian system and hormonal effectors of diapause. Furthermore, comparison of brains from aphids reared under different photoperiods provided some evidence of the involvement of some of these cells in the process that governs diapause. Together, our findings support the existence of a complex but traceable neuroendocrine network in the aphid brain, where circadian clock neurons, neurosecretory centers, and hormonal outputs are functionally and anatomically connected. We are thus closer to establish a detailed map of the regulatory network that controls diapause in aphids, both at the molecular and cellular levels. Moreover, as the process is likely to be (at least partially) conserved in insects, advances in the completion of this map offers an excellent model to explore the evolutionary adaptations of diapause regulation in other insect species.

Linking Changes in Pollinator Behaviour with Their Effect on Male Fitness in Buzz-Pollinated Flowers

Melo L¹, Vallejo Marin M¹

¹Department of Ecology and Genetics - EBC - Uppsala University

POSTER SESSION 3 - **P03.052**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Pollinators play a fundamental role in shaping patterns of pollen transfer that ultimately influence plant fitness. In floral ecology and evolution, pollinators are often treated as a "black box," with limited understanding of how specific behaviours impact reproductive outcomes. In buzz-pollinated systems, bees extract pollen by vibrating flowers, a behaviour that is innate even in naive individuals. After buzzing, bees groom their bodies to collect pollen, storing it in specialized structures (corbiculae) on their hind legs. This groomed pollen is effectively removed from the pool available for pollination, potentially reducing male fitness. In this study, we examine how variation in bee behaviour during floral visits affects pollen dispersal, using *Bombus terrestris* and *Solanum sisymbriifolium* as a model system. By conducting controlled experiments in flight arenas, we aim to provide novel insights into how pollinator behaviour influences pollen fate.

Materials and Methods: To assess pollinator behaviour and pollen transfer, we exposed 5 flowers of *S. sisymbriifolium*, a nectarless, buzz-pollinated plant native to South America, to individual *B. terrestris* bees from captive colonies. Floral visits were recorded in flight cages using a video camera and synchronized audio from a microphone placed inside the cage to record buzzing sounds. We categorized behaviour into distinct actions (e.g., buzzing, grooming on flower, grooming while flying, flying, other) using Behavioural Observation Research Interactive Software (BORIS). Duration and frequency of each behaviour per flower visit were recorded. After each trial, bees were

freeze-killed and their corbicular pollen loads were quantified. The anthers and stigmas from visited flowers were collected to estimate the pollen remaining in the anthers and pollen grains deposited on the stigma.

Results: We analysed behaviours from 52 bees from 10 colonies interacting with 182 flowers. When accounting for total trial duration, bees that allocated a higher proportion of time to buzzing and grooming behaviours were more likely to visit a larger number of flowers. Buzzing and grooming behaviours were positively correlated ($r = 0.83$), especially when grooming occurred on flowers. Grooming while flying was also positively associated with flower visitation rate ($r = 0.68$). Among the behaviours analysed, buzzing ($r = 0.63$) and grooming emerged as key predictors across the different behavioural categories. In contrast, total foraging time was weakly correlated with the different behaviours individually (all $r \approx 0.21-0.35$), suggesting that bees differ not only in how much time they forage but in how they allocate time across specific actions.

Conclusions: This study highlights the ecological importance of how bees allocate time during foraging, not just how long they forage. Behaviours such as buzzing and grooming emerge as key components influencing the outcome of floral visitation. This behavioural investment likely affects pollen transfer dynamics and plant reproductive success, highlighting the role of bee behaviour, which, even at a small scale, can affect the success of plant-pollinator interactions.

Nest weave pattern in weaverbirds: a sexual signal selected through sensory drive?

POSTER SESSION 3 - **P03.031**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Nests are extended phenotypes that are primarily shaped by natural selection to protect offspring. In some species, however, they are conspicuous and elaborate, and therefore visible to predators. One hypothesis to explain this apparent paradox is that nests could also evolve through sexual selection. While extended phenotypes are increasingly recognized as potential signals, very few studies have tested this theory on a comparative scale. Here, we investigated the potential role of sexual selection in shaping nest visual patterns, focusing on scale-invariance, a property describing how patterns remain visually similar across spatial scales. The sensory drive hypothesis, mediated by a processing bias, predicts that nests whose scale-invariance matches that of natural habitats are processed more easily and appear more attractive. The processing bias hypothesis is new and still lacks empirical validation. Using phylogenetic Bayesian multilevel models in a comparative analysis of weaverbirds (Aves: Ploceidae),

we tested whether their nests have evolved to match the scale-invariance of natural habitats. We quantified the deviation of nest scale-invariance from a range of putative selection optima. We then assessed whether interspecific variation in this deviation is explained by mating system and sexual size dimorphism, two proxies of sexual selection. For both proxies, the estimated parameters had the greatest magnitude for the same putative optimum, supporting a role for sexual selection. Moreover, this optimum aligns with natural habitat values, consistent with the sensory drive hypothesis. Our study provides support for the idea that extended phenotypes, such as nests, may evolve through sensory-driven sexual selection acting on complex pattern geometry. However, our findings highlight the challenge of designing a highly specific test for this hypothesis in the context of visual patterns, and call for further research linking pattern perception and sexual selection.

Non-canonical organisation of the olfactory system in the ant *Temnothorax longispinosus*

Mendes C^{1,2}, Pala C², Darras H¹, Foitzik S¹, Martelli C²

¹Institute For Organismic And Molecular Evolutionary Biology, Johannes-Gutenberg University Of Mainz,

²Institute of Developmental biology and Neurobiology, Johannes-Gutenberg University of Mainz

POSTER SESSION 3 - **P03.047**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Communication is essential for group coordination in social animals. In ants, chemical communication is important for regulating division of labour among castes and relies on the detection and processing of chemical cues. Queens and males primarily contribute to reproduction, while workers perform tasks such as brood care, nest defence, and foraging. Odorant receptors (ORs) mediate the conversion of chemical signals into neuronal activity, which is subsequently processed in the brain. This is carried out through a highly conserved olfactory system, where Olfactory Receptor Neurons (ORNs) expressing the same unique OR send projections from the antennae to the same glomerulus in the antennal lobe (AL)—the primary olfactory processing centre in the insect's brain. This spatially precise connectivity constitutes the canonical one-OR:one-ORN:one-glomerulus model of the olfactory system, which usually implies a fixed number of glomeruli in the AL.

Deviations from the canonical one-OR:one-ORN paradigm exist in some species, including ants. In the clonal raider ant (*Ooceraea biroi*), co-expression—more precisely, co-transcription—of OR genes has been observed, particularly among genes belonging to the same tandem array. This different regulation of expression prompts key questions: Do factors relating to worker and colony identity influence OR expression? And does that ultimately determine AL anatomy? In this study, we aim to elucidate the organizational logic of the olfactory system in ants by relating differences in worker brain anatomy and OR gene expression, and their behavioral role in the colony.

Hymenopterans, particularly ants, have undergone an expansion of their OR repertoire, which is hypothesized to facilitate the detection of complex cuticular hydrocarbon profiles and pheromones. In the ant *Temnothorax longispinosus*, workers exhibit age-dependent division of labour; young workers care for the

brood, while older workers primarily forage. However, task allocation is flexible, and workers can switch tasks depending on the requirements of the colony. Our genomic analyses indicate that the *T. longispinosus* genome encodes approximately 460 OR genes, which are arranged in tandem arrays, with many ORs differentially expressed in the antennae of nurses and foragers. We quantified the number of glomeruli in the AL of *T. longispinosus* workers through immunohistochemistry and 3D reconstructions. Six monogynous colonies of different sizes were selected for the experiments. Whole-colony dissections were performed to assess intra-colony variation in glomeruli numbers, enabling the evaluation of individual-level plasticity. Furthermore, inter-colony comparisons were carried out to identify whether AL organization is influenced by factors such as queen genotype, colony size, and environmental factors. Additionally, newly eclosed workers were compared to older workers to assess whether AL organization is fixed post-pupal stage or undergoes plastic changes that are associated with age and division of labor.

According to the one-OR:one-ORN:one-glomerulus model, the number of glomeruli in the AL should correspond to the number of OR genes. However, preliminary results—based on 60 workers from the six colonies—reveal a mismatch between the number of glomeruli and OR genes. Furthermore, differences in glomeruli numbers were observed between newly eclosed ants and older workers, indicating a possible role of developmental plasticity in young adults. Moreover, inter-individual variation in glomeruli numbers was found within workers of the same colony. This variation in the neural architecture may have evolutionary advantages and enhance colony fitness and adaptability. Ultimately, this project will provide new insights into the evolution and plasticity of olfactory systems in insects.

On the evolution of sound-related sexual dimorphism in dung beetles

Roggero A¹, Natta G¹, Zanon A¹, Fabbriani F², Fiorito A¹, Laini A¹, Rolando A¹, Palestini C¹

¹Department of Life Science and Systems Biology, ²Independent Researcher

POSTER SESSION 3 - **P03.020**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Many aspects of the evolution, ecology, and ethology of dung beetles concern sexual dimorphisms. In many species, the variously shaped horns of males define distinct “maior” and “minor” morphs, whereas they may be smaller or entirely absent in females. Hornless species of dung beetles also exist, and in these sexual dimorphisms are limited to less evident morphological traits (e.g., the presence of spines and teeth on the foretibiae of males, and wider and armless foretibiae in females). Several species of dung beetle are capable of acoustic communication (via stridulation), with relevant intraspecific and interspecific behavioural implications. The aim of the present research was to examine sound-related sexual dimorphism by evaluating if (and how) this trait diverges in horned and hornless species.

Materials and methods: We examined two Palearctic dung beetles: the horned *Copris umbilicatus* (25 individuals from Cantagallo, Bisenzio Valley, N Apennines, Tuscany), and the hornless *Geotrupes mutator* (16 individuals from Mocchie, Susa Valley, W Alps, Piedmont). Although these taxa are not phylogenetically close, they are both large tunnelers, and the adults produce distress calls when disturbed. The stridulatory organs (pectrum and pars stridens) are located on the inner portion of the hind coxa and coxal cavity in *G. mutator* (Geotrupini), and on the distal part of the sternites and elytra in *C. umbilicatus* (Coprini). In accordance with traditional morphometric techniques we used maximum pronotum width as a good proxy of body size. To assess stridulatory organ structure we counted the number of ridges present in a 0.5 mm wide band of the pars stridens. Distress calls in each individual were recorded and the sounds analyzed by testing

the A and B subunits separately (i.e., the sequences of pulses with opposite phases).

Results: Morphometric analysis revealed a clear sexual dimorphism in the stridulatory organ of *G. mutator*, with a significantly higher number of ridges on the pars stridens in females than in males. Sex-dependent differences were also detected in the distress call as the number of peaks in the subunit A was higher and the amplitude of the peaks in the subunit B lower in female specimens. In *C. umbilicatus*, the stridulatory organ showed no evident sexual dimorphism, with males and females presenting approximately the same number of ridges on the pars stridens, and emitting very similar stridulations.

Conclusions: The stridulatory organs (and relative signals) evolved independently and many times in Coleoptera, predation pressure and sexual selection being the main drivers of these morphological innovations. Our results suggest two distinct evolutionary pathways at work. i) *C. umbilicatus* has developed a horn sexual dimorphism but no sexual dimorphism in the stridulatory organs or stridulations emitted, while *G. mutator*, a hornless species, has instead developed a sound-related sexual dimorphism. This may reflect an evolutionary “trade-off” at work: either you invest in the development of one dimorphism, or you invest in the development of another, but not in both. ii) The stridulatory organs of the two species are located in different parts of the body: on the legs in *G. mutator*, on the wings in *C. umbilicatus*. The legs of the males of the hornless *G. mutator* has a tooth that the females lack. Therefore, in this species, the sound-related sexual dimorphism could actually part of the development of sexual dimorphism of the legs.

Patterns and Colors Just Don't Mix: Plumage Color Evolution Trends in a Songbird Clade

Henson K¹, Creighton M¹, Sinnott-Armstrong M¹

¹Duke University

POSTER SESSION 3 - **P03.055**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Feathers are highly specialized structures that display a wide range of colors and patterns commonly used in avian communication, especially in signaling a bird's individual quality to potential mates or rivals. Two complex types of feather coloration are melanin-based patterns (such as spots and stripes) and structural colors (such as blue or glossy black). Both types of coloration require precise coordination of keratin and melanin production not only within each feather, but also across feathers to achieve a uniform appearance in overall plumage. We hypothesized that patterned plumage and structural coloration each signal similar information about a bird's individual quality and are therefore unlikely to co-occur within species. Additionally, we hypothesized that the presence of carotenoid-based coloration such as red, yellow, and orange would have no effect on the evolution of either trait, as these pigments are acquired dietarily and likely signal different types of information. To test these hypotheses, we examined plumage traits across Estrildidae and Viduidae, two closely related passerine families with highly diverse plumage colors and patterns. We

scored for the presence or absence of melanin-based patterning, structural coloration, and carotenoid coloration from over 200 museum specimens across both families. We reconstructed ancestral states for each trait and used phylogenetic mixed modeling to test for correlated evolution of color traits. Consistent with our hypothesis, we found a negative association between patterned plumage and structural coloration in extant species. Additionally, habitat type and presence of carotenoid coloration significantly predicted the evolution of structural coloration, but not patterned plumage. Finally, a test for correlated evolution using Pagel's method revealed that the likelihood of either patterned or structural plumage evolving depends strongly on the state of the other trait. Our results suggest that patterning and structural coloration are redundant signals in Estrildidae and Viduidae and that this trend may be present in other avian groups, though future studies are needed to test this. To our knowledge, this study is the first to examine the relationship between structural color and plumage patterns across a group of closely related birds.

Personality development in wild house mice: Evidence for a nutrition-dependent sensitive period early in life

Walasek N¹, Jovicic M², Günther A^{2,3}

¹Institute For Biodiversity And Ecosystem Dynamics, University Of Amsterdam, ²Research Group Behavioural Ecology of Individual Differences, Max Planck Institute for Evolutionary Biology, Plön, Germany, ³University of Hildesheim

*POSTER SESSION 1 - **P01.015**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Changing environmental conditions pose challenges to organisms, for example, by disrupting access to food. Across species and traits, animals use phenotypic plasticity to adjust to such changes. Previous work has demonstrated that wild house mice are able to adjust stress coping to changing food quality within just three generations. However, we do not know when during ontogeny changing conditions induce phenotypic adjustments. We tested experimentally when during ontogeny (as fetus, newborn, weanling, or late adolescent) a food switch between standard and high-quality food shapes personality development (stress coping and stress perception) in cage-housed, wild house mice (*Mus musculus domesticus*). Personality

traits were assessed in the Open Field and the Elevated Plus Maze at different time points during ontogeny (weaning, early adolescence, late adolescence, and adulthood). We highlight two key findings. First, the fetal life stage might be a sensitive period for stress coping in response to experiencing decreases in nutritional quality. Second, experiencing an increase in nutritional quality may slow the age-related switch towards a passive stress-coping strategy. Our study contributes towards understanding the complex relationships between development, nutrition, and personality. These insights can inform future studies investigating how nutritional fluctuations shape individual behavior and population dynamics in the wild.

Rapid color change in cichlid fishes: Using computer vision to study behavioral diversity and evolution

Häge J^{1,2}, Kratochwil C^{1,2}

¹Helsinki Institute of Life Science (HiLIFE), University of Helsinki, ²Faculty of Biological and Environmental Sciences, University of Helsinki

POSTER SESSION 3 - **P03.027**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: The ability of some animals to rapidly change colors, sometimes within seconds, is a fascinating adaptation to interact with the biotic and abiotic environment. In cichlids, a very diverse and species-rich fish family, this ability serves as a powerful mode of social communication. By fading and enhancing dark (melanic) markings on the face and body, these fishes can signal sexual interest to potential mates or aggression towards competitors. In addition, cichlids may change some of the same markings to achieve background matching or the motion dazzle effect, which can help them avoid detection and tracking by others, including potential predators or prey. However, due to the challenge of quantifying color change behavior, it is poorly understood how color change ability and behavior differ between cichlid species and individuals, as well as how they are linked to different environmental stimuli and factors. Overcoming this barrier will help shine a light on many aspects of the behavioral ecology of cichlids and the evolution of behavioral traits.

Materials and methods: Here, we developed a computer vision pipeline to quantify the state of different melanic markings of cichlid fish in high temporal resolution under laboratory conditions. We show that rapid color change can be elicited by manipulating the environmental factors cichlids use as cues, such as ambient light intensity and background brightness. To deliver stimuli to fish in small aquaria with consistency and precision, we developed purpose-built experimental setups that use single-board computers to coordinate both stimulus

delivery and data acquisition. The current dataset encompasses such recordings for multiple cichlid species with individuals differing in sex, age, reproductive states, and color morph and will provide a solid foundation to expand these analyses to freely behaving animals in social contexts.

Results: The data collected proves that it is possible to use computer vision to characterize rapid color change responses to ecologically relevant environmental stimuli and identify general trends in how different markings respond, as well as compare such responses between species and individuals. Our preliminary findings include a thorough investigation of how the same marking responds in different color morphs of a species, as well as multiple types of responses to the same environmental stimuli. Our data supports consistent responses within and between individuals and provides evidence for interactions between specific markings, environmental stimuli and social status.

Conclusions: Investigating the evolution of behavior remains one of the biggest challenges in biology. Studying behaviors via rapid color change, where behavioral and motivational states of an animal can be extracted from video frames, holds significant potential to link behavior, genetics, and environmental context. Here, we showcase a computer vision pipeline that can acquire a direct phenotypic (behavioral) read-out in a highly automated manner that will be useful for investigating environmental stimuli such as light and background, as well as social stimuli.

Role of niche choice in rapid host adaptation of a global pest

Musiolik P^{1,2}, Nariman N^{1,2}, Kaltenpoth M², Xu S¹

¹Johannes Gutenberg University, ²Max Planck Institute for Chemical Ecology

POSTER SESSION 3 - **P03.035**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The niche choice mechanism, which describes the process of organisms choosing different microenvironments matching their phenotype, affects individual survival and reproductive success. It can influence many ecological and evolutionary processes by promoting rapid local adaptation and maintaining genetic diversity. The evolution of niche choice and its role in individual adaptation remain largely unknown and the question of how niche choice and its evolution affect insecticide resistance in phytophagous insects is yet to be addressed. Using experimental evolution, metagenomics and microbiome analyses, this study aims to investigate how oviposition choice affects resistance evolution and overall fitness in Colorado Potato Beetles (CPB), a notorious global pest.

We evolved beetle populations for at least 12 generations in separate cages in a controlled greenhouse environment. A 2x2 factorial design was implemented: presence or absence of plant treatment variation (niche difference, ND+/ND-) and presence or absence of oviposition choice (OC+/OC-). In ND+ treatments, beetles could choose between insecticide-treated and water-treated potato plants; in ND- both trays were of identical plant quality. In OC+, larvae were placed at their maternal oviposition site, whereas they were placed in random distribution in the OC- treatment to disregard the female's choice. Fitness, oviposition behavior and survival were recorded in each generation. Additional bioassays were performed to test oviposition preference and insecticide resistance. These bioassays were performed on offspring beetles that were reared on untreated plants to identify possible genetic mechanisms behind this behavior and exclude maternal effects. So far, we performed the choice assay for generation F1 and the toxicity assay for F1 and F4.

The choice bioassay revealed a trend toward oviposition preference on water-

treated plants by F1 females whose parents (F0) experienced the oviposition choice treatment (OC+). The choice index for this group indicated avoidance of insecticide-treated hosts, while females from the other three treatment groups showed no such pattern. This trend narrowly missed statistical significance ($p = 0.0546$). Feeding preference showed no significant differences between treatments ($p = 0.6$). Preliminary toxicity assay results indicated increased resistance to imidacloprid in F4 populations compared to the founder generation across all treatments. The strongest increase in LC50 values was observed in the insecticide-only group, followed by the “no choice” (OC-) and “oviposition choice” (OC+) treatments and lastly the water-only treatment. These findings support the hypothesis that the presence of niche choice behavior may slow the evolution of insecticide resistance.

For bioassays, preliminary findings showed a trend toward avoidance of insecticide-treated hosts in the F1 populations of OC+ treatment. Since the larvae for bioassays were reared exclusively on untreated plants to avoid maternal imprinting effects, this avoidance behavior might be genetic or result from random variation. The insecticide resistance increased across all treatments by generation F4, most prominently in the insecticide-only treatment. These results may indicate a potential trade-off between behavioral avoidance and physiological resistance: beetles that evolved under oviposition choice conditions may rely more on insecticide-treated host plant avoidance, thereby reducing selection pressure for physiological resistance. In contrast, beetles lacking the choice behavior may be more exposed to insecticides, promoting faster evolution of resistance mechanisms. Further long-term data- involving microbiome analyses and genomic profiling- is currently gathered to test this hypothesis.

Sex differences in parental cognition and response to offspring signals in birds

Caro S^{1,2,3}, Hinde C, Van Oers K⁴, Velasco A⁵, van Mastrigt T⁴, Villareal R², Wu K², Hofmann H²

¹Adelphi University, ²University of Texas at Austin, ³Wageningen University & Research, ⁴Netherlands Institute of Ecology (NIOO-KNAW), ⁵National Museum of Natural Sciences

POSTER SESSION 3 - P03.036, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Mothers, fathers, and offspring clash over how much food offspring should get. Both fathers and mothers benefit from having well-fed offspring, but each would prefer their partner shouldering more, ideally all, of the burden of care, leading to sexual conflict over offspring provisioning. Different selective pressures acting on males and on females may have caused the evolution of sex differences in how parents respond to offspring begging signals when making provisioning decisions. However, despite knowing much about what choices parents make overall, we know less about broad patterns of sex differences in parental response to begging or about the neurobiological and cognitive basis underlying parental choices. Here, we combined an experimental study on wild great tit parents (*Parus major*) to explore sex differences in how quickly and confidently parents choose an offspring to feed, with a comparative study across 31 bird species to explore the evolutionary drivers of sex differences in parent-offspring communication. In our experimental study, we found that great tit parents' decision speed was impacted by offspring starvation

risk, decision complexity and whether parents chose to feed a preferred chick or not, in a sex-dependent manner. Specifically, females make slower decisions than males and moved food between chicks more before committing. In our meta-analysis, we found that species varied in whether males or females were more responsive to offspring begging, and that this is correlated with pair bond strength. In species with weaker pair bonds, such as the great tit, females are more responsive to offspring begging. Conversely, males are more responsive to begging in species with stronger pair bonds, such as the barn owl which normally mates for life. Together, these results suggest that variation in sexual conflict may affect the evolution of within-species variation in parent-offspring communication, and that this variation may be caused by differences in how males and females integrate sensory information and reach a decision threshold. More generally, they show the benefits of combining multiple approaches when exploring the causes of behavioral diversity.

Sex-specific voluntary fasting in the ontogeny of size dimorphism in snakes

Kratochvíl L¹, Ehl J¹, Starostova Z¹, Bauerova A¹, Kubicka L¹

¹Charles University

POSTER SESSION 3 - **P03.048**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Variation in energy intake is often viewed as a response to ecological constraints or food availability, with sex-specific reproductive investment driving divergent growth and the evolution of sexual size dimorphism. But what if causality runs in the opposite direction? Could intrinsic, sex-specific growth trajectories shape feeding behaviour instead? We tested this idea in a four-year laboratory study of the sand boa (*Eryx colubrinus*), a strongly female-larger species, under continuous food availability. Growth, feeding, and body condition were tracked over time, and growth was experimentally manipulated via exogenous testosterone. Our results reveal that growth in body length proceeded independently of immediate food intake. Instead, feeding and fasting were tightly regulated by body condition: snakes stopped feeding upon reaching an upper condition threshold, and resumed only after condition declined to a lower limit. These thresholds were shared across sexes and hormone treatments. Males fasted more often and for longer,

months lasting periods than females. Faster-growing females depleted energy reserves faster, which led to more regular feeding. Testosterone had no effect on growth or feeding in males, but slowed (defeminized) growth and reduced feeding frequency in females—supporting the idea that feeding is driven by growth-mediated shifts in body condition. These findings challenge classical energy-budget models. Instead, they support a model where feeding serves to maintain body condition within narrow limits, and growth rate determines how quickly those limits are reached. Extended fasting in males may be an adaptive strategy to reduce the risks associated with feeding in snakes—such as predation or injury—while female growth shaped by fecundity selection necessitates more frequent feeding. This study highlights the need to integrate behaviour, morphology, and physiology to understand the evolution of sexual size dimorphism and sex-specific life-history strategies.

Testing the Darwin-Bateman Paradigm: Anisogamy as a Fundamental Driver of Sex Role Evolution in Birds

Garcia Miranda O¹, Székely T²

¹University Of Debrecen, ²University of Bath

POSTER SESSION 3 - P03.017, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The evolution of sex roles—mating systems, parental care, and sexual size dimorphism—has been a central question in evolutionary biology since Darwin. Over the past 50 years, multiple hypotheses have been proposed to explain sex role variation, including sexual selection, natural selection via niche partitioning, and demographic factors such as sex-specific mortality and adult sex ratios. However, despite extensive research, the foundational hypothesis of sex role evolution—the role of anisogamy—has never been rigorously tested across taxa.

The Darwin-Bateman paradigm posits that anisogamy, the inherent disparity in gamete size between sexes, drives fundamental differences in reproductive investment, competition, and parental care. To empirically test this long-standing theory, we assembled the most comprehensive dataset to date on male and female gamete sizes in nearly 200 bird species, a group with unparalleled data on mating systems and parental strategies. Using cutting-edge phylogenetic comparative methods, we

modeled the relationship between anisogamy (gamete size bias) and multiple sex role components. Additionally, we conducted phylogenetic path analysis to assess the relative explanatory power of anisogamy compared to alternative hypotheses, including demographic constraints and ecological niche partitioning.

Our preliminary results reveal significant patterns, suggesting that anisogamy may play a more central role in shaping sex roles than previously recognized. At ESEB 2025, we will present the full results, offering the first large-scale empirical test of a fundamental yet unverified evolutionary theory. By integrating detailed empirical data with advanced phylogenetic modeling, this study provides a novel framework for understanding sex role evolution. While our findings are grounded in birds, they hold broad implications for the evolution of reproductive strategies across the tree of life.

The effects of dietary innovation on metabolism during the evolution of cognitive enhancement in *Heliconius* butterflies.

Kersh-mellor R¹, Montgomery S¹, Nicholls B²

¹University Of Bristol, ²University of Sussex

POSTER SESSION 3 - **P03.026**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The colonisation of a new dietary or ecological niche can drive sensory and cognitive adaptation, but the production and maintenance of neural tissue comes at a significant energetic cost. Understanding how selection balances the costs and benefits of neural investment is a key issue in evolutionary biology. Such investment may be offset by reductions in other metabolically demanding tissues or processes, with consequences for life history traits and behaviour. Alternatively, behavioural innovations that increase energy intake may relax these constraints, permitting greater investment in energetically costly brain regions. Among butterflies, *Heliconius* are unique in that they consume both nectar and pollen as adults. This dietary innovation provides a consistent and protein-rich resource that supports their extended lifespan and is associated with improved cognitive performance and the expansion of mushroom bodies – brain structures implicated in learning and memory. These elaborated brain regions are likely to impose increased metabolic demands. It is hypothesised that the shift to pollen feeding in *Heliconius* alleviated the energetic constraint typically limiting neural expansion, enabling increased investment in cognitive architecture. This project aims to test this hypothesis by comparing metabolic investment in *Heliconius* to that of non-pollen-feeding *Heliconiini* at multiple levels.

At the whole-organism level, resting metabolic rates are being estimated via flow-through respirometry, using custom-designed chambers and infrared video tracking to identify periods of rest. Trial experiments have successfully demonstrated the feasibility of this approach, and data collection is currently ongoing across a wide phylogenetic sample. To complement organismal-level measures, oxygen consumption rates of dissected whole brains are being quantified using high-throughput microrespirometry. While early trials revealed challenges due to the size and respiration rate of butterfly brain tissue, the protocol has been refined to focus on basal respiration. Once final adjustments are made, this will enable efficient comparative analysis across multiple species. Finally, activity of cytochrome oxidase, a metabolic enzyme and proxy for ATP usage, will be measured in whole brains and mushroom bodies using histochemical staining to assess regional differences in energy metabolism. Together, these approaches will help elucidate whether dietary shifts such as pollen feeding allow for increased energy allocation to neural tissue, and to what extent cognitive elaboration is constrained or enabled by energetic factors. These data will contribute to a broader understanding of how ecological innovation can influence brain evolution and behavioural complexity.

The effects of migration-related genotype on swimming behavior in rainbow trout *Oncorhynchus mykiss*

Redon L^{1,2}, Ejjite A², Lindeza A², Lopes J², Magné G², Kause A¹, Primmer C², Prokkola J¹

¹Natural Resources Institute (Luke), ²Organismal and Evolutionary Biology Research Program, Faculty of Biological and Environmental Sciences, University of Helsinki

POSTER SESSION 3 - **P03.042**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Migration occurs across a wide range of taxa, with each group exhibiting several distinct strategies. Salmonid fishes are a prime example of diversity in migratory behavior, as differences in migration strategies are observed not only between species, but also between ecotypes of the same species. While some salmonids are residents (i.e., non-migrating), the life cycle of anadromous (i.e., migrating) salmonids typically consists of migrating from freshwater, where they hatched, to the sea, where they feed and grow, and then back to freshwater to spawn, often in their natal river. In anadromous *Oncorhynchus mykiss* (steelhead), spawning migration timing is a variable trait, as two separate runs are observed: one in summer and one in winter. Both ecotypes spawn in the spring, indicating strong differences in the energetic costs of spawning migration, as the summer-migrants reside in the river for several months before spawning. The *greb1L* locus on chromosome 28 has been associated with variation in spawning migration timing in *O. mykiss*, yet the physiological and behavioral processes underlying this link remain unknown. Thus, disentangling the roles of genetic, physiological and environmental factors governing migratory behavior, as well as their interactions, is key to

understanding the evolution and diversity of migratory strategies in salmonids. In this study, 144 immature females from an aquaculture strain of rainbow trout (originating from a California Steelhead population) were reared in common garden conditions and implanted with accelerometry loggers to measure routine activity. Individuals were homozygous either for the summer- or for the winter-run *greb1L* allele. We hypothesized that the summer-run allele of *greb1L* would be associated with a “fat-storing” phenotype, characterized by reduced activity and increased fat deposition to conserve energy for a longer spawning migration. A food-restriction treatment was also implemented to test whether behavior is modulated by food availability in interaction with *greb1L* genotype. Activity was measured for 24 consecutive hours every six days from January to May 2025. Growth in body mass and length, and the total amount of fat reserves—quantified via Dual-energy X-ray absorptiometry (DEXA) imaging—were also assessed to evaluate differences in energy allocation to somatic growth and fat deposits. The results provide insights into the genetic bases of phenotypic characteristics associated with alternative migratory behaviors in a key migratory fish species.

The evolution of socially-mediated dispersal favours the emergence and maintenance of distinct social and dispersal strategies

Prigent I¹, Mullon C¹

¹Université de Lausanne

POSTER SESSION 3 - **P03.050**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Kin selection is an important mechanism for the evolution of cooperative behaviours across multiple taxa. While limited dispersal can foster kin selection by generating a genetic correlation between cooperating individuals, it also increases competition among relatives, constraining the evolution of cooperation. Prior theory has explored the co-evolution of dispersal and cooperation but typically assumes dispersal is independent of social cues. Here, we use mathematical modelling to examine whether socially-mediated dispersal, where individuals adjust their dispersal based on social context, can mitigate kin competition and thus enhance cooperation. We model the joint evolution of: (i) the probability of cooperating within social groups; and (ii) the probability of dispersing conditional on the number of individuals that have cooperated within the group, leading to a reaction norm

for dispersal. We show that when the probability of dispersal increases with the number of cooperators, cooperation is favoured due because it increases the fitness of relatives. The joint evolution of the two traits can lead to the differentiation of two types of individuals, one that always cooperates and another that never does. Although both types evolve dispersal norms such that they disperse more often when there are more cooperators in the group, cooperators evolve a steeper norm, reflecting greater sensitivity to their social environment. Our study shows that dispersal norms in response to an individual's social environment can depend on that individual's own social tendency, which can help explain how dispersal proclivities may differ between individuals and between environments within a single population.

The role of social learning in speciation by sexual selection: the case of a poison frog

González-Santoro M¹, Richards-Zawacki C¹, Yang Y²

¹University of Pittsburgh, ²University of South Florida

POSTER SESSION 3 - **P03.028**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

After 150 years of research, the topic of speciation by sexual selection remains a frustrating endeavor, in which, empirical evidence fails to meet theoretical predictions. An outstanding progress was recently achieved by showing that sexual learning at early stages of development (imprinting), a phenomenon that occurs during parental care, facilitates mating traits divergence and the preferences for them, the initial steps of reproductive isolation. Imprinting leads females to mate with males that look like their parents (and usually themselves), a process that hinders gene flow between divergent phenotypes. Imprinting also leads males to compete against individuals that look like themselves, relaxing competition pressures and promoting co-existence among divergent phenotypes. Much less understood is the

role that social learning at other life stages and by different tutors - a common process in animals - plays in the facilitation of behavioral reproductive barriers. To fill this gap, I performed female mate choice and male territorial aggression experiments in both field conditions and a captive bred colony of the poison frog *Oophaga pumilio*, a species that shows rapid and dramatic divergence in a mating trait (color). I will show results of two experiments that suggest that individuals' sexual biases are modified by their social environment (i.e., the phenotypes that they interact with) both during development and after sexual maturity. This suggests that certain social environments can rapidly trigger speciation, providing a unique path towards the generation of biodiversity in our planet.

To migrate or not to migrate? Exploring the genomic basis of the partial migratory behavior in bats

POSTER SESSION 3 - P03.021, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Migration is a widespread phenomenon across the animal kingdom, involving the seasonal, long-distance movement of individuals in search of favorable environmental conditions. This complex behavior is supported by a suite of morphological, physiological, and behavioral adaptations, and while it is often environmentally triggered, increasing evidence suggests that it is also genetically regulated. Partial migration, where migratory and resident individuals coexist within the same population, is thought to represent an evolutionary intermediate towards obligate migration, shaped by opposing selective pressures. However, despite decades of research on migratory ecology and orientation, the genetic and molecular underpinnings of migration remain poorly understood, especially in mammals. Here, we investigated the genomic basis of migration in a flying mammal, the lesser long-nosed bat (*Leptonycteris yerbabuenae*), a partially migratory, nectar-feeding species that maintains tight ecological interactions with columnar cacti and agaves. In this species, one group of female mates in southwest-center Mexico (October–December) and migrates northward in spring to give birth in the Sonoran Desert. A second group remains resident in central Mexico, mating and giving birth during the summer. All adult males are also resident in central Mexico and mate with both groups of females. Using RAD-seq, we found no evidence of neutral genetic structure across these populations, consistent with high gene flow and panmixia, despite their opposite migratory movements.

Both migratory and resident groups showed similar demographic histories, with an initial period of stability followed by a decline starting ~30,000 years ago during the Last Glacial Maximum. This period coincides with a shift in the distribution of their main food plants and the emergence of migratory behavior. Despite the lack of genetic structure, we identified 23 genomic regions potentially involved in determining migratory behavior. These regions were detected using an iterative and complementary approach based on F_{ST} and Tajima's D , focusing on candidate loci showing signatures of selective sweeps (e.g. F_{ST} values several orders of magnitude above the genome-wide average). Ten of these regions also showed signatures of positive selection in the migratory group. The annotation showed some of the candidate regions contained genes related to nervous system and immune function, some of which have been previously implicated in migratory behavior in other vertebrates, suggesting functional convergence. Our findings support the hypothesis that migration in *L. yerbabuenae* has a genetic basis shaped by strong diversifying selection acting on specific genomic regions. The stable coexistence of migratory and resident females within a panmictic population may reflect a form of balancing or disruptive selection operating under a “migratory threshold” model. In this scenario, males could influence phenotypic transitions across generations through their homogenizing genetic contribution. Overall, this study highlights the potential of bats as valuable models for understanding the evolutionary origins and genomic underpinnings of migratory behavior.

Transcriptomic mapping of diapause in the aphid brain

Morales Poole J¹, Martínez Torres D¹, Barberà Solà M¹

¹Institute for Integrative Systems Biology, Universitat de València – CSIC

POSTER SESSION 3 - **P03.030**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

All organisms on Earth have evolved biological rhythms as an adaptation to face alternation of periods of favorable and unfavorable environmental conditions, at various temporal scales. Diapause is a state of seasonal dormancy, common in insects and other arthropods, that allows them to overcome recurring periods of adverse environmental conditions. Facultative diapause is triggered by biotic and abiotic factors that precede the arrival of the harsh season. The most prevalent signal that announces the arrival of the inimical season is day length (photoperiod). The capability of many different organisms to detect changes in photoperiod and produce a response is known as photoperiodism. Perception of changes in photoperiod triggers a, yet only partially characterized, cascade of molecular, neurologic and endocrine events that lead to the activation of diapause in insects. Different studies have shown the involvement of the circadian clock machinery and of specific clock neurons, as well as of some neurohormones (e.g. insulin-like peptides) and neuropeptides. Aphids are hemimetabolous plant sap sucking insects that have been classically used as models to study photoperiodism. Their life cycles consist of several generations of viviparous parthenogenetic females followed by a single sexual generation, with males and oviparous sexual females. The sexual generation is induced by the shortening of photoperiod after the summer. The outcome of the sexual phase are cold resistant eggs that allow aphids to survive the winter. Thus, induction of the sexual phase is the way aphids enter diapause. Classical studies

showed that the aphid brain is the center of photoperiod perception, signal integration and elaboration of the adequate response. Previous research from our group has identified putative elements of the regulatory network involved in aphid diapause at the levels of perception, integration and signal transduction. Aiming at filling the gaps in the signalling pathway of aphid diapause we compared expression between aphid brains in Long Day condition (promoting parthenogenesis) and aphids in Short Day condition (inducing sexual morphs) by two complementary approaches: 1) scRNAseq of aphid brains and 2) in toto RNAseq time course of aphid brains. The scRNAseq produced the first atlas of an aphid brain and describes different cell groups. Regarding the regulation of diapause, we found genes coexpressed in the Insulin Producing Cells, Dorsal Neurons and Lateral Neurons, pointing out the signalling pathways that may be involved in diapause regulation. The in toto brain RNAseq time course contributed to the identification of circadian regulated genes and provided candidate pathways to regulate diapause. These results complement with the localization by Immunohistochemistry of different neuropeptides and proteins in the aphid brain. Altogether, we are closer to establish a detailed map of the regulatory network that controls diapause in aphids, both at the molecular and cellular levels. Moreover, as the process is likely to be (at least partially) conserved in insects, advances in the completion of this map will help to map diapause in other insect species.

Warmer climate disrupts pace-of-life syndromes through ontogenic changes of activity levels in the common lizard *Zootoca vivipara*

Mouret N^{1,2}, Bestion E¹, Paquet M¹, Cote J²

¹Station d'Ecologie Théorique et Expérimentale (SETE), ²Centre de Recherche sur la Biodiversité et l'Environnement (CRBE)

POSTER SESSION 3 - **P03.025**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Ongoing climate change has drastic and diverse effects on organisms. In particular, warmer temperatures are assumed to accelerate the pace of life of individuals, and therefore developmental and senescence rate. Because behavioural traits and their among-individual variability are involved in eco-evolutionary dynamics, a better understanding of how climate is susceptible to alter their ontogeny is required. Here we focus on the effect of a warmer climate on the ontogeny in individual activity level in the common lizard *Zootoca vivipara*. Activity is more susceptible to changes in climate given its link with pace of life syndrome and metabolic rates and such changes may have strong consequences on population and community dynamics. For the last 10 years, common lizards are maintained in semi-natural mesocosms experiencing either current or ~2°C warmer climatic conditions and individually monitored for activity level and life history traits over their lifetime. Using this database, we explored how warmer climates impact age-related changes in the mean and the within and between individuals variability of activity levels as well as the mechanisms potentially involved in such

changes (differential survival and plasticity). We found activity to be partly heritable and repeatable only on parts of the lifetime resulting from contrasting patterns of between and within individuals variability across ages and climates. We found that activity level decreased with age, both as a result of within-individual changes and of the selective disappearance of more active individuals, more pronounced in the warmer climate. Overall, the syndrome linking activity level and fitness outcomes was climate-dependent, mostly because only less active individuals accelerated their pace-of-life in warmer climates. Considering its close links with physiology and pace of life syndromes, observed changes of the ontogeny of activity with climate may have consequences on the population dynamics and persistence of this generalist predator species with potential cascading effects on species at lower trophic levels and whole ecological networks .

Chemosensory evolution at the origin of inquilinism in the bee louse fly (*Braula coeca*)

Delarue A¹, Sandoz J¹, Yassin A¹, Carcaud J¹, Bastide H¹

¹Université Paris-Saclay, CNRS, IRD, UMR Évolution, Génomes, Comportement et Écologie

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

Living beings are not isolated and interact with each other. These interactions are often mediated by chemical odorants but how the evolution of the olfactory system can determine intra- and inter-specific interactions remains unclear. A peculiar example is the queen mandibular pheromone (QMP) in *Apis mellifera*, which inhibits the development of the ovaries in the conspecific workers (hence leading to social cohesion) and also in other insect species (hence protecting the colony). Of the different parasites of *Apis*, only one, the blind and wingless bee louse (*Braula coeca*), paradoxically spends its entire life cycle as an inquiline in the colony, clinging to the thorax or head of bees, with a clear preference for the queen at the end of the summer. We have sequenced its genome and confirmed that it is a basal branch of the *Drosophilidae* family, closely related to *Drosophila melanogaster*. To understand how *Braula coeca* has found an evolutionary

means of circumventing the anti-ovarian effect of QMP, we investigated the evolution of multiple chemosensory gene families. We found the bee louse has lost almost half of the olfactory receptor drosophilid repertoire, including some that respond to QMPs in *D. melanogaster*. By combining multiple functional approaches, including behavioral assays in the field, electroantennography, heterologous gene expression of *Braula* receptors in *D. melanogaster* empty neurons, and CRISPR-Cas9 genome editing to induce *B. coeca* mutations in *D. melanogaster*, we are currently testing the hypothesis that the rapid evolution of *Braula coeca*'s ORs has protected it from the anti-ovarian effects of QMP, enabling it to reproduce in an essentially sterilizing environment. Primary results are supporting this hypothesis, hence providing significant insights on how changes in chemosensory genes promote the evolution of inter-specific interactions.

Convergent evolution of pain insensitivity in a new *Heliophobius* species

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

The African mole-rat family, Bathyergidae, is a family of subterranean rodents that exhibit extraordinary physiological adaptations to life underground. Among these, variation in pain sensitivity is particularly striking (Eigenbrod et al., 2019). We have discovered a population of *Heliophobius* mole-rats from Tanzania's Usambara Mountains that are uniquely insensitive to both acid and capsaicin, two compounds that typically induce robust pain behaviors (algogens) when injected into the animals' hindpaw. Until now, this exact phenotype was only reported in the naked mole-rat (*Heterocephalus glaber*; Park et al., 2008; Eigenbrod et al., 2019). The newly identified *Heliophobius* population, like *H. glaber*, shows no nocifensive response to these stimuli. Interestingly, however, they remain sensitive to AITC (allyl isothiocyanate), a pungent compound that activates the TRPA1 ion channel, indicating that some pain pathways remain functional. In contrast, their closest known relative, Emin's mole-rat (*H. emini*), shows normal pain responses to all three algogens, similar to the mouse and reflecting the typical mammalian nociceptive phenotype. This stark interspecific contrast provides a powerful natural experiment to investigate the evolution and molecular basis of nociceptive variation.

To elucidate the genetic mechanisms underlying this difference, we generated high-quality, chromosome-level genome assemblies for both *Heliophobius* taxa using PacBio HiFi long-read sequencing and Hi-C chromatin contact mapping. We also generated genome assemblies for other Bathyergid species to enable broader comparative analysis. Using an updated naked mole-rat reference genome for alignment and annotation, we identified two amino acid substitutions in the

SCN9A gene (encoding the voltage-gated sodium channel Nav1.7) in the Usambara *Heliophobius*. These substitutions, located in complementary domains of the pore region of the channel, are identical to those previously shown to underlie acid insensitivity in *H. glaber*. Notably, these substitutions are absent in *H. emini*, strongly suggesting a case of convergent molecular evolution leading to shared nociceptive phenotypes.

In addition to functional genomics, we conducted phylogenomic analyses to clarify the evolutionary relationships of this newly identified population. Genome-wide markers generated via ddRAD sequencing, along with mitochondrial cytb sequences, place the Usambara mole-rat in a distinct clade, separate from both *H. emini* and *H. argenteocinereus*. Our sample from this population clusters with individuals previously assigned to *H. kapiti* (Uhrova et al., 2022), a taxon of uncertain status. Taken together, the genomic, phenotypic, and phylogenetic evidence supports recognizing *Heliophobius kapiti* as a distinct species.

This newly recognized species expands our understanding of African mole-rat diversity and provides a unique model for studying convergent evolution in sensory biology. The geographic and phylogenetic proximity of this taxon to the naked mole-rat (*H. glaber*)—despite their belonging to different genera—makes the Usambara mole-rat an exceptional system for investigating how similar selective pressures can independently shape complex traits such as pain insensitivity. Our findings demonstrate that extreme sensory phenotypes can evolve multiple times within the same family and offer a window into the genomic architecture that enables such adaptations in mammals.

Ecological divergence and post-eclosion brain development shape visual performance in *Heliconius* butterflies

Borrero J¹, Laborieux L¹, Wright D¹, Lozano-Urrego D¹, Rueda-Muñoz G¹, Pardo-Díaz C², Salazar C², Montgomery S³, Merrill R¹

¹Ludwig Maximilian University of Munich, ²Universidad del Rosario, ³University of Bristol

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Linking ecological divergence to neural and behavioural variation is central to understanding the evolution of behavioural diversity. In the closely related butterflies *Heliconius cydno* and *H. melpomene*, ecological speciation across forest light environments is associated with pronounced differences in visual system morphology. *H. cydno*, which inhabits darker, closed-canopy forests, exhibits larger eyes and greater neural investment in vision-associated brain regions than *H. melpomene*, a species found along brighter forest edges. However, the behavioural and developmental implications of these visual system adaptations remain poorly understood. Using an optomotor response paradigm, we assessed visual acuity in both species across four stages following adult emergence. We found that visual acuity increases with age in both species, with *H.*

cydno consistently exhibiting higher resolution. These ontogenetic improvements in visual performance coincide with the onset of key life-history behaviours, such as male courtship and female oviposition, suggesting that early adult neurodevelopment may facilitate behavioural maturation. To explore the neural basis of these patterns, we quantified brain development using confocal microscopy and a novel deep-learning segmentation pipeline to analyse over 80 brain samples. Our analyses revealed significant species differences in optic lobe volume that align with the enhanced visual acuity observed in *H. cydno*. By integrating ecological context, neuroanatomy, and behaviour, our findings demonstrate how environmental pressures may drive neural specialization and shape behavioural trajectories early in the speciation process.

Evolution of Taste Neurons and Behaviour

Arguello R¹, Saint-Leandre B, Bertolini E, Pascual J, Baticle T, Sgammeglia N, Rodriguez Crespo D, Clara von Philipsborn A, Auer T

¹Queen Mary University Of London

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

How sensory perception evolves as species diversify and change ecological specialization is poorly understood. In chemosensation, historically more attention has been placed on olfaction, leaving open important questions about how taste and contact chemosensing evolve and the behavioural differences that they drive. We have carried out a comparative single-cell transcriptomic (snRNA-seq) study of neurons in the taste appendages (forelegs and proboscis) of closely-related *Drosophila* species with distinct ecologies (*D. melanogaster*, *D. simulans*, and *D. sechellia*). Analyses of the neuron transcriptomes revealed unambiguous homologous cell-types. Among the most pronounced changes were lineage-specific switches in sex-biased gene expression. These findings bolster recent observations made at the bulk tissue level but narrow them to specific neuron populations and point towards functional nervous system differences evolving between the sexes. Cross-species analysis revealed the most quickly evolving neurons in the forelegs are chordotonal neurons (vibration sensors) followed by mechanosensory and gustatory

neurons. In the proboscis, the most rapidly evolving neurons are a population of uncharacterised neurons that express nicotinic acetylcholine receptors. To investigate the functional consequences of these gene expression changes in specific neuron populations, we focused on a striking species difference involving a putative pheromone receptor belonging to the pickpocket channel family, *ppk15*. In *D. melanogaster* and *D. simulans*, *ppk15* is expressed in leg and proboscis neurons. In *D. sechellia*, the proboscis expression of *ppk15* has been lost. Using a panel of transgenic reagents and *ppk15* null mutants generated for the three species, we are using calcium imaging to measure physiological responses and characterising feeding and mating phenotypes. Our results point towards *ppk15* being a conspecific pheromone receptor that's expression has been recently lost specifically from the proboscis of *D. sechellia*. Together, our analyses underscore the utility of combining global and single gene studies to advance our understanding of how taste and taste-related behaviours evolve over short evolutionary timescales.

Genetics and environment shape vocal frequency variation in birds

Kirschel A¹, Lukhele S¹, Poyiadji A¹, Sebastianelli Arbelaez M^{1,2}, Conradie S³, vonHoldt B⁴

¹University Of Cyprus, ²Uppsala University, ³University of the Witwatersrand, ⁴Princeton University

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Vocal frequency in animals is shaped by both intrinsic and extrinsic factors. A role of the environment in driving acoustic adaption is widely supported. Climate may also shape frequency both directly, via physiological effects on the vocal tract, but also indirectly through morphological adaptation to climate and temperature-dependent physiological constraints on song frequency. But much variation in vocal frequency has evolved over time between related species that cannot be attributed to environmental effects. Determining the relative effects of genetic and environmental factors and their interactions on vocal frequencies is a complex undertaking hitherto seldom attempted. Here, we assess the relative effects of body mass and bill length, abiotic and biotic environmental factors, sex, and genome-wide ancestry on song frequency in

tinkerbirds across a hybrid zone in Southern Africa. Using path analysis, we determine the extent of direct and indirect effects of the environment and ancestry on vocal frequency. Our results confirm the strong negative effect of body mass on song frequency as well as the indirect effect of temperature via its effect on body mass. Ancestry and sex also affect vocal frequency, and we identify genes associated with frequency by performing a genome-wide association study. Yet we found little evidence for any acoustic adaptation to the vegetation structure of the environment. Overall, our study has shown that temperature-associated variation in morphology in accordance with Bergmann's rule directly affects vocal frequency in birds, but there is also a genetic component that explains further variation among species.

Heterochrony in orthodenticle expression is associated with ommatidial size variation between *Drosophila* species

Posnien N¹, Torres-Oliva M², Buchberger E¹, Buffry A³, Kittelmann M³, Guerrero G⁴, Sumner-Rooney L⁵, Gaspar P³, Figueras Jimenez J⁶, Casares F⁴, Arif S³, Nunes M³, McGregor A⁶, Almudi Cabrero I⁷

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Compound eye size in insects, determined by ommatidia number and size, is a key visual adaptation to diverse environments and lifestyles. Despite its ecological importance, the genetic and developmental mechanisms controlling eye size evolution remain poorly understood. We identified an X-linked region contributing to larger eyes in *Drosophila mauritiana* compared to *D. simulans*, primarily due to increased ommatidia size. We combine fine-scale mapping and gene expression analysis to investigate candidate genes within this region. We report earlier expression of the developmental gene orthodenticle (*otd*)

during ommatidial maturation in *D. mauritiana*. Functional analyses in *D. melanogaster* confirm its role in ommatidia size and organization. Furthermore, a species-specific *otd* eye enhancer recapitulates the observed heterochronic expression shift. Finally, we identify potential downstream targets of *Otd* differentially expressed between *D. mauritiana* and *D. simulans*. Our findings implicate altered *otd* expression timing in the evolution of compound eye size, providing novel insights into the genetic regulation of visual system adaptation in insects.

How to build a bigger brain?

The cellular basis of expanded mushroom bodies in *Heliconius* butterflies.

Alcalde Anton A^{1,2}, Hebberecht Lopez L^{1,2}, McMillan O², Montgomery S^{1,2}

¹University of Bristol, ²Smithsonian Tropical Research Institute

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Brain expansion is a critical dimension of animal evolution, often linked to ecological innovation and behavioural complexity. Our understanding of the ways in which neurodevelopmental variation determines how neural systems are constructed is largely restricted to model species. Emerging case studies in more diverse species can now provide insights into the cell developmental pathways and patterns of genetic regulation that shape changes in neuron number, brain size and structure. One such case study are the Neotropical butterflies, *Heliconius*. Among butterflies, *Heliconius* exhibit a unique behavioural profile, as they are the only genus known to actively feed on pollen. They learn and remember the location of pollen sources, revisiting them in a spatially and temporally faithful manner reminiscent of the trap-line foraging behaviours observed in some bees. Compared to their most closely related genera in the tribe Heliconiini, *Heliconius* butterflies display enhanced visual memory, and possess expanded mushroom bodies, brain structures associated with learning and memory in insects. *Heliconius* mushroom bodies contain up to 8 times more Kenyon cells, the intrinsic mushroom body cells, than other Heliconiini, and show evidence of specialisation for visual processing. This combination of behavioural and neural specialisation makes *Heliconius* and their outgroups an excellent system for investigating the development and evolution

of nervous systems, and particularly the expansion of the mushroom body.

Using a comparative approach across two *Heliconius* and four representative Heliconiini outgroups, we generated multiple developmental time series to explore how mushroom bodies develop from newly hatched larvae to adulthood. Our time series includes 12 developmental stages. Specifically, we analysed patterns of cell proliferation within each species, by quantifying the number of progenitor cells, using immunohistochemistry, EdU labelling, and the growth of the Kenyon cell population. Our results reveal striking differences in the number of proliferating cells between *Heliconius* and non-*Heliconius* species, suggesting major changes in the cell biology of neurogenesis, and the potentially the evolution of a new intermediate progenitor cell which amplifies Kenyon cell production. Analysis of Heliconiini species with intermediate levels of Kenyon cells in adulthood suggest this was a continuous process of refining the degree of replicative division of progenitor cells. This research provides deeper insight into the mechanisms underpinning the expansion of a brain structure essential for learning and memory in insects. Currently, we are expanding this work using single-nuclei transcriptomics to uncover the molecular identity of the proliferating cells and the regulation of brain expansion.

Life in dim light: The evolution of vision in deep-sea fishes

Fogg L^{1,2}, Policarpo M^{2,3}, Marshall J⁴, Skowronska-Krawczyk D^{5,6}, Cortesi F^{4,7}, de Busserolles F⁴, Salzburger W²

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

Background: Visual systems have evolved across diverse photic environments, from brightly-lit coral reefs to the perpetual darkness of caves and the deep sea. In vertebrates, vision is accomplished by photoreceptor cells in the retina, which detect light via visual pigments (opsins). There are two main types of photoreceptors: cones for the detection of bright light and rods for dim light vision. It is well-established that visual capabilities are adapted to ecological demands. For example, deep-sea and nocturnal species often exhibit rod-dominated retinas, sometimes to the complete exclusion of cones. In the most extreme conditions, such as in cavefishes living in complete darkness, vision can be lost altogether. Vision has been pushed to the limits of functionality in some deep-sea species, where persistent low temperatures, high-pressure conditions, and extremely limited light present unparalleled challenges for a visual system. Our work has focused on understanding how vision evolves and adapts to the extreme conditions of the deep sea.

Materials and Methods: We focused on the largest vertebrate class, fishes, employing transcriptomics, histology, and comparative genomics to investigate over 500 species, and integrating insights on developmental and evolutionary timescales. First, we studied the development of vision in deep-sea fishes using retinal transcriptomics and histology. Then, we examined the evolution of opsin genes in dim light environments, by applying a comparative genomic approach across ray-finned fishes. Finally, to understand the limits of vision in the deep sea, we examined an extreme case – the Greenland shark, a deep-sea shark which is also the longest-living vertebrate – using genomics, transcriptomics, histology, RNAscope, and in vitro opsin regeneration.

Results: Firstly, we discovered that deep-sea fishes follow a different developmental pathway to most vertebrates. Typically, during development, vertebrates initially feature a cone-dominated retina, and rods are added later. However, larval deep-sea fish possess "hybrid" photoreceptors that integrate rod and cone features into a single cell type. This finding challenges traditional paradigms of photoreceptor classification and vertebrate visual development. Next, using a large-scale genomic analysis of opsin genes, we revealed that dim light environments have consistently driven a contraction of the opsin gene repertoire across the phylogeny of fishes. Specifically, we observed highly contracted repertoires in cave-dwelling, electrogenic and deep-sea fishes. This work reveals genetic mechanisms underlying adaptive evolution in the deep sea and a striking case of convergent adaptation. Finally, we demonstrated that the Greenland shark retains an intact visual system well-adapted for life in dim light, despite having parasitized eyes, extreme longevity and a low light environment. Indeed, we found visual adaptations typical of deep-sea species, confirmed the presence of key visual cell populations, and showed that rod-specific vision genes were intact and robustly expressed. Moreover, despite being centuries old, the examined specimens showed no signs of retinal degeneration. This suggests remarkable evolutionary resilience and the maintenance of sensory function over centuries.

Conclusions: Our findings provide new insights into how vertebrate vision adapts to extreme environments via developmental, genetic and cellular mechanisms. More broadly, they illustrate how ecological pressures shape sensory evolution, offering a framework for understanding the diversification of visual systems across vertebrates.

Modality-specific memory enhancements in *Heliconius* butterflies result from specific mushroom body expansion, rather than increased investment in the sensory pathways

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

How organisms process the world is closely linked to the species-specific demands of their ecology and life histories. Neural architecture changes have allowed species to exploit new sensory niches, facilitating evolution of huge behavioural diversity across the animal kingdom. Indeed, changes in weighting towards particular senses often results in corresponding investment shifts in the sensory processing structures. The Neotropical butterfly tribe Heliconiini offer a tractable system for studying how changes in neural circuitry have enabled adaptive shifts in behaviour. Across the short time scale of the evolution of Heliconiini, there is huge variation in the size of mushroom bodies (insect learning and memory centre). In particular, the genus *Heliconius* have greatly expanded mushroom bodies in comparison to their Heliconiini relatives. This expansion has been closely linked to shifts in behaviour and life history. This includes active pollen feeding, a dietary innovation that has afforded *Heliconius* increased lifespan and fecundity. *Heliconius* possess up to eight times more intrinsic mushroom body neurons than the other Heliconiini clades, with a notable increase in the volume of the mushroom body calyx receiving afferent visual input. This increased visual investment in the mushroom bodies is proposed to have co-occurred with evolution of *Heliconius*' systematic pollen-foraging behaviour, whereby the same pollen resources are visited with high fidelity. This behaviour is thought to rely heavily on the formation of spatial and visual-scene memories. Indeed, *Heliconius* have spatial memory and significantly enhanced stability of long-term visual memories in comparison to their outgroup Heliconiini relatives. Until now, however, it has not been known whether this cognitive enhancement in *Heliconius* was specific only to visual memories, or how their behavioural differences were accounted for in the wider neural architecture.

To address this question, I will present two studies. Firstly, we assessed modality-specific memory performance across representative *Heliconius* and outgroup Heliconiini species. Secondly, we measured differences in investment in the sensory system upstream of the mushroom bodies. In the first study, we carried out long-term olfactory memory assays in two *Heliconius* and two outgroup Heliconiini species, comparing their performance to existing visual-memory data. We found that olfactory long-term memory is present to the same degree across Heliconiini. Notably, however, comparisons between olfactory and visual memory revealed that *Heliconius* exhibit a greater retention of visual, but not olfactory long-term memories compared to outgroup Heliconiini. This indicates that selection has acted in a modality-specific manner in *Heliconius*, rather than increasing overall memory. In our second study, we used a combination of eye dissection, immunohistochemistry and neural injections to quantify investment in the sensory structures (eye morphology, visual and olfactory neuropils and the patterns of sensory projection pathways) across Heliconiini species. Overall, these analyses revealed that, although *Heliconius* have visual-specific enhancements in long-term memory, there are no concomitant increases in investment in visual architecture. In contrast, in several cases, we even found outgroup species to have higher investment in the visual components than *Heliconius*. Overall, this suggests that the massive mushroom body expansion in *Heliconius* occurred independently of the rest of the sensory processing circuitry. These results present a rare example of selection driving a highly specific and localised shift within a brain region, facilitating the evolution of a novel behavioural trait.

Neuron Number in Fish Brains: Evolutionary Insights into Computational Power

Dionigi F¹, Musilová Z, Němec P

¹Charles University

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Neuronal counts serve as a critical measure for assessing brain computational capacity across vertebrate taxa, shedding light on the evolutionary trajectories of brain complexity. Yet, systematic data on neuron numbers in fish remain sparse, despite their immense diversity. This study employed the isotropic fractionator method to explore neuronal distribution in cartilaginous, lobe-finned, and ray-finned fishes, emphasizing evolutionary patterns.

Our findings highlight notable evolutionary divergence: teleost fishes, despite their compact brain architecture, exhibit remarkably high neuronal densities, particularly in the cerebellum, which houses over 50% of all brain neurons. This contrasts with lungfishes and basal ray-finned fishes, which display modest neuronal counts.

Among teleosts, benthic species demonstrate lower cerebellar neuron numbers, suggesting a correlation between habitat and cerebellar function in spatial orientation.

Intriguingly, weakly electric teleosts reveal extreme evolutionary adaptations in neuronal distribution, with cerebella holding over 95% and telencephala less than 0.5% of total neurons. Mormyrid fishes, in particular, exhibit cerebellar neuron counts rivaling those of large mammals, likely reflecting the demands of active electrolocation as a sensory modality. These findings underscore the cerebellum's role in the optimization of neural processing for complex behaviors, contributing to a broader understanding of brain evolution in vertebrates.

Phylogenetic insights into the emergence of brain anatomy and cognition.

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Cortical convolutions are a hallmark of large mammalian brains, where increased brain size correlates with a steep rise in folding. These folds exhibit species-specific patterns, often mirroring the arrangement of cortical regions with distinct functions and connections. While the notion of cortical folding as a result of mechanical instability from brain growth has gained traction in the past decade, the consensus remains that folding patterns are genetically determined.

Our study explores to what extent mechanical morphogenesis shapes the development and evolution of the primate cortex. We reconstructed cerebral surfaces for more than 70 primate species, and connectomes of the underlying structural connectivity for several New World and Old World monkeys. Using phylogenetic comparative methods, we estimated ancestral states across this large variety of primate brains, and validated our findings with an independent dataset of endocasts. We developed novel methods to assess similarity of folding, cortical thickness and

connectivity patterns across species. We found that these patterns are strikingly similar between brains with similar volume no matter if they come from far branches of the phylogenetic tree. In contrast, the brains of 2 close cousins with different brain volumes show very different folding, cortical thickness and connectivity patterns.

Finally, we investigate if these mechanical processes that shape the landscape of folds and connections could also influence function and behaviour. We collected comprehensive behavioural and physiological data for all our species and found similar behavioural traits across species with similar brain volume, independent of their phylogenetic relationship.

Our findings suggest that mechanical morphogenetic processes significantly influence the organisation, anatomy, and connectivity of the primate brain, potentially impacting cognitive functions leading to the emergence of similar behavioural traits across distant evolutionary branches.

Single-nuclei transcriptomics reveals neural cell type innovation associated with mushroom body expansion in Heliconiini Butterflies.

Cicconardi F¹, Farnworth M¹, Montgomery S¹

¹University of Bristol

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Throughout animal evolution, the diversity of behaviour and cognitive abilities has been underpinned by evolutionary innovations and the specializations in neural systems. These innovations often arise through the acquisition of novel features built upon pre-existing neural architectures. Emerging models of brain evolution increasingly emphasise that selection acts on the local refinement of established functions—replicating and modifying existing cell types and circuits—within generally conserved networks. While current data reveal patterns consistent with neural specialisation supporting behavioural evolution, the specific mechanisms underlying cell type evolution within brain circuitry remain largely unexplored. The diversity and experimental tractability of insects make them particularly well suited for integrative studies of brain evolution within well-resolved phylogenetic and ecological contexts. Among the most variable structures in the insect brain are the mushroom bodies (MBs), major integrative centres that receive input from primary sensory regions, and are critical for associative learning and memory. MB size is highly variable across insects, ranging from ~4% to 60% of total central brain volume, largely due to changes in the number and morphology of Kenyon cells, the intrinsic MB neurons. Across insects, major increases in MB size have occurred independently multiple times, but the most recent of these expansions evolved within the Heliconiini butterflies.

The tribe Heliconiini, which includes the genus *Heliconius* which is unique among butterflies due to a suite of derived behavioural and physiological traits, including novel dietary and foraging strategies, extended lifespans, and delayed reproductive senescence. Central to these adaptations is a unique dietary shift: adult *Heliconius* actively collect and digest pollen, acquiring essential amino acids that are

unavailable to other Heliconiini. This innovation is coupled with the evolution of a spatial foraging strategy akin to trap-lining—a spatially and temporally precise strategy, also found in bees, that relies on visual memory. These behavioural specialisations are accompanied by a dramatic expansions of the MBs, including over a fourfold increase in volume relative to brain size, and up to an eightfold increase in Kenyon cell number. These expansions, primarily in visual processing regions, correlate with enhanced performance across a range of cognitive assays, including improved long-term memory and complex visual discrimination tasks.

In this study, we applied combinatorial barcoding single-nuclei transcriptomics to whole brains of *Heliconius melpomene* and *Dryas iulia* to generate comparative cell type atlases. Using three technical replicates comprising pooled whole brains and isolated Kenyon cell clusters, we generated over 300,000 high-quality single-nuclei transcriptomic profiles. Cell types were annotated semi-automatically by cross-species integration of data from five insect brain atlases. This approach enabled us to group, for each species, over 70 distinct cell types within different types of glial cells, Kenyon cells, optic lobe neurons, odorant projection neurons, and other neuron types, with just a few remaining unknown. Our analysis revealed extensive similarities in cell type identity, but with marked species-specific differences in Kenyon cell abundance and complexity. Additionally, we identified sex-biased differences in glial and optic lobe cell types, suggesting potential links to divergent mating strategies. This comprehensive atlas offers a valuable resource for investigating the evolution of neural cell types and the mechanisms underpinning behavioural innovation in *Heliconius*, and across insects.

The evolution of diversity in rhythm: Developing cross-species metrics to assess the evolutionary dynamics of rhythm and syntax in birdsong

Leon X¹, Creanza N¹

¹Vanderbilt University, Department of Biological Sciences

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Oscine songbirds (Order: Passeriformes) primarily use their songs for mate attraction, and their songs can evolve in response to sexual selection, with females showing a preference for males with certain song features that indicate their quality as potential mates. Previous studies have demonstrated that certain features of birdsong, such as song learning accuracy and syllable repertoire size, can signal stress incurred during early development. Females have also shown a preference towards males who are proficient at these same song traits, together suggesting that high quality learned songs are associated with greater reproductive success. Similarly, it has been hypothesized that rhythm, or the temporal patterns of songs, may function in mate choice as an indicator of fitness used by females to assess mate quality. For example, female birds in two studied species have been shown to prefer songs that are more temporally stereotyped, suggesting that rhythmicity might function in mate choice. Rhythm is an evolutionarily complex neurobehavioral trait: to produce a rhythmic song, neurons must fire at precise times in key brain regions. Practicing singing their song over time may lead to more stability and regularity of these neuronal firing patterns, and thus more rhythmic songs as a bird gets older; thus, age-dependent stability of the neural circuitry could suggest that rhythmicity may be an indicator of survivability, underscoring its potential utility as a reliable indicator of fitness. While researchers have begun investigating the temporal dynamics in birdsong in a few species, no studies have investigated how rhythm in birdsong may have changed over evolutionary history. Here, we provide new cross-species

metrics to analyze learned behaviors at scale and investigate the evolutionary dynamics of rhythm and syntax in birdsong across the Oscine clade. We developed a set of metrics to quantify rhythm and syntax in a way that is comparable across many species of songbirds, measuring 1) timing regularity using the distribution of inter-onset intervals, 2) syllable repetition by calculating the proportion of unique syllables, and 3) phrase-level repetition by measuring the compressibility of the song syntax strings. We applied these new methods to a subset of species using song recordings obtained from Xeno-canto and the Macaulay Library. Then, using Chipper, a song analysis software, we segmented the songs into syllables and obtained data necessary for the temporal metrics, and we also obtained the syntax of the songs manually for our syntax repetition metrics. We calculated the median values of each trait for each species to perform phylogenetic comparative analyses. Interestingly, we found that the rhythm traits of our three metrics have similar predicted ancestral states and evolve in similar patterns to one another, largely following a Brownian motion model of evolution (Blomberg's $\kappa = 0.826 - 1.051$). While closely related species tend to have more similar rhythm patterns, rhythm is not perfectly conserved, suggesting that there might be other factors, such as ecology or life history, that may be driving the evolution of rhythmicity. We have conducted preliminary phylogenetic analyses to assess the effects of other selective pressures on the patterns of rhythm evolution across the Oscine songbird phylogeny, providing the first in-depth analysis of rhythmicity on a phylogenetic scale, including the pace of change over time and in relation to life history and other traits.

The genetic basis of neural circuit evolution for *Drosophila* mate preferences

Behrman E¹

¹Dartmouth

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Behaviors that arbitrate interspecies courtship are at the crux of evolutionary barriers between species. Species- and sex-specific pheromone profiles in *Drosophila* have rapidly diversified that signify species' identity to encourage courtship among conspecifics and discourage interspecies courtship. The dominant pheromone produced by *Drosophila melanogaster* females is an aphrodisiac to their males, but the same chemical cue inhibits courtship in male *D. simulans*, whose females do not produce that pheromone. We identify a gene that has evolved to reshape the neural circuit that processes this pheromone and change

the male's response from attraction to repulsion. We assess how this gene changes the anatomical and physiological properties of specific neurons in the circuit between the species to produce divergent behaviors. Additionally, we examine intra-species variation in genetic and environmental factors that alter female production of and male attraction to the pheromone cue. Together, this provides a unique mechanistic understanding of the genetics underlying neural circuit evolution and how the corresponding behavior affects evolutionary processes in the wild across different timescales.

Visual System Adaptations Underlying the Evolution of Flower-Visiting Behavior in *Drosophila*

Ishikawa Y¹, Katsura M¹, Kawamura K¹, Fujii K¹, Arikawa K², Kinoshita M²

¹Nagoya University, ²The Graduate University for Advanced Studies

MEETING ROOM 115, August 18, 2025, 10:30 AM - 12:30 PM

The evolution of animal behavior can generate novel interspecies interactions, potentially reshaping ecosystems. One notable example is the emergence of flower-visiting behavior in insects, which has established new animal-plant interactions. Insects appeared long before flowering plants evolved and later developed flower-visiting behaviors following the adaptive radiation of angiosperms. Today, flower-visiting insects are responsible for pollinating approximately 90 percent of angiosperm species, playing a vital role in maintaining terrestrial ecosystems. However, the mechanisms by which this behavior evolved in insects, and specifically what novel brain functions and neural systems enabled this transition, remains largely unknown. To address this question, we focused on *Drosophila elegans*, a species that has acquired flower-visiting behavior for breeding and feeding, diverging from its fruit-breeding ancestors. Because *D. elegans* is amenable to genome editing and closely related to the non-flower-visiting model organism *D. melanogaster*, it serves as a useful model for investigating the neural mechanisms underlying the evolution of flower-visiting behavior.

D. elegans preferentially visits blue *Ipomoea* flowers in the wild. To identify the sensory modalities involved, we analyzed behavior of newly emerged flies under controlled conditions. *D. elegans* was found to preferentially visit artificial *Ipomoea*-like fabric flowers, photographs of *Ipomoea* flowers, and even blue circular paper disks presented

with green, beige, and yellow disks with similar brightness all lacking any floral scent. These findings suggest their strong reliance on vision, particularly color cues, for flower recognition. Notably, *D. melanogaster* did not visit any colored disks under the same experimental conditions, implying that brain functions related to visual and color information processing are crucial for the evolution of flower-visiting behavior.

To understand how visual processing systems may have changed during this behavioral evolution, we compared the visual systems of the two species. Transmission electron microscopy revealed that the rhabdomeres of R8 photoreceptor cells, which are sensitive to blue or green light depending on the ommatidial subtype, are larger in *D. elegans*. Electroretinogram recordings further showed that *D. elegans* exhibits relatively higher sensitivity to blue light. These findings suggest that *D. elegans* has evolved a visual system adapted to detect blue *Ipomoea* flowers. Genome editing experiments demonstrated that R7 and/or blue-type R8 photoreceptor cells are essential for this flower-visiting behavior. Together, our results indicate that evolutionary changes in the neural system, beginning with these photoreceptors, played a key role in the emergence of flower-visiting behavior. Since many flower-visiting insects rely on visual cues, our findings provide novel insights into the brain functions and neural adaptations contributing to the evolution of flower-visiting behavior.

Why did the human brain size evolve? A way forward

González-Forero M¹, Gómez-Robles A²

¹Konrad Lorenz Institute For Evolution And Cognition Research, ²University College London

MEETING ROOM 115, August 18, 2025, 2:00 PM - 5:00 PM

Why the human brain size evolved has been a major evolutionary puzzle since Darwin but addressing it has been challenging. A key reason is the lack of research tools to infer the causes of a unique event for which experiments are not possible. We suggest that analogous problems have been successfully addressed in other disciplines using what has been recently termed simulation-based inference. Following that approach, we outline a strategy to address why the human brain size evolved: hypotheses are expressed in mechanistic models that yield quantitative predictions for evolutionary and developmental trajectories of brain and body sizes, the predicted trajectories are compared to data, and

models are chosen by their ability to explain the data. We discuss a recently published model that makes quantitative predictions for evolutionary and developmental trajectories of brain and body sizes for six hominin species and compare the model predictions to data, finding that the model recovers many aspects of hominin evolution and development. Counter-intuitively, the human brain size evolves in this model as a spandrel or by-product of selection for something else, namely, fertility-determinant traits. Our analysis indicates that simulation-based inference offers a way forward to infer why the human brain size evolved.

A la carte seed harvesting: *Messor barbarus* selects durum wheat genotypes

Plessis C¹, Rocher A^{1,2}, Compan F¹, Romiguier J³, David J¹, Fréville H¹

¹AGAP, Univ. Montpellier, CIRAD, INRAE, Institut Agro, ²DIASCOPE, Univ. Montpellier, INRAE, ³ISEM, Univ. Montpellier, CNRS, IRD

POSTER SESSION 1 - P01.230, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biotic interactions between plants and insects can significantly shape their reciprocal evolution. Seed predation by ants can be viewed as either a mutualistic or antagonistic interaction, depending on the balance between its costs and benefits for the plant species. In Mediterranean agroecosystems, harvester ants specialize in collecting seeds, including those of cultivated cereals. Yet their potential role in shaping crop traits remains largely unexplored. Durum wheat (*Triticum turgidum* ssp. *durum*), a key Mediterranean crop domesticated from wild emmer (*Triticum turgidum* ssp. *dicoccoides*), has undergone major morphological changes during domestication, particularly in reproductive organs such as spike and seeds. However, whether interactions with seed predators like harvester ants contributed to the selection specific plant phenotypes remains unknown. In this study, we investigate the genetic architecture underlying durum wheat susceptibility to ant predation, and then test in a separate experiment whether *M. barbarus* foraging behavior reflects plant genetic variation. Building on observations from a field experiment, we investigated the phenotypic and genetic determinants of seed predation by the harvester ant *Messor barbarus* across a panel of 180 durum wheat inbred-lines exhibiting high phenotypic and genetic diversity. First, we visually assessed spike predation by *M. barbarus* on 95 genotypes within ant foraging areas and conducted a genome-wide association study (GWAS) using SNP markers to uncover the genetic basis of harvester ant predation on durum wheat. Based on the identified genomic regions, we examine the functions of candidate genes potentially involved in ant predation. We also designed a cafeteria experiment using 208 spikes from 26 genotypes placed at the entrance of eight nests to validate our genetic findings and

investigate how spike and seed traits influence ant preferences. We estimated the heritability of wheat on ant preference using the spike mass loss after 24 and 42 hours and tested whether ant preference is partly genetically determined in wheat. Then, we analysed the selective pressure exerted by ants on spike and seed traits, such as morphological characteristics and protein content, to better understand the selective pressures at play.

We detected a significant Quantitative Trait Loci (QTL) on chromosome 2A, whose allelic variation explained 21% of the observed phenotypic variation in predation rates by *M. barbarus*. This region encompasses a 3.6 Mb segment that includes a chromosomal inversion between wild emmer wheat and durum wheat, and 46 candidate genes, from which one MYB transcription factors that could be involved in cuticle and chemical trait regulation. This QTL was validated by the cafeteria experiment: ants preferentially removed spikes from genotypes carrying the preferred allele detected from the GWAS analysis. Furthermore, ants preferentially started to harvest seeds from shorter spikes, with some ants sometimes bringing the whole spikes into the ant nest. While spike morphology did affect ant choice, we did not find any significant correlation between seed morphology or protein content and predation levels.

Our study provides the first evidence that harvester ants exhibit genotype-specific preferences in durum wheat, and that these preferences are linked to a major QTL on chromosome 2A. These findings suggest that ant foraging may be an underappreciated factor in cereal crop evolution, providing new perspectives to better understand interactions between seed predators and crops.

Altruism or Selfishness? Evolution of floral behavior in response to neighboring kinship.

Tomizuka H¹, Yamawo A², Tachiki Y¹

¹Tokyo Metropolitan University, ²Kyoto University

POSTER SESSION 1 - **P01.199**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Kin recognition in plants may induce behavioral plasticity, including changes in floral traits. Recent studies have shown that plants growing with genetically related neighbors tend to produce larger floral displays than those with unrelated individuals. This pattern has been interpreted as altruism, where plants incur the cost of larger flowers to attract more pollinators to the patch, thereby increasing the pollination success of neighboring kin. However, whether such behavior consistently represents altruism remains unclear.

Materials and methods: We developed an evolutionary model in which plants adopt one of two floral display tactics depending on the genetic relatedness of neighboring individuals. The model incorporates ecological parameters such as pollinator foraging preferences for large flowers and plant dispersal ability. We used individual-based simulations to explore the evolutionary outcomes of these plastic floral strategies.

Results: Our results predict the evolution of two distinct strategies facilitated by kin recognition: altruistic behavior involving increased floral display toward kin, and a free-rider strategy involving reduced floral display toward non-kin. Increasing floral display toward kin evolved when pollinators showed weak preference for individual plants with large floral displays or when kin

recognition was highly accurate. Under these conditions, larger floral displays enhanced group-level pollinator attraction, thereby increasing the pollination success of neighboring individuals—consistent with altruistic behavior. In contrast, reducing floral display toward non-kin evolved when pollinator preferences for individual large-flowered plants were weak. This strategy can be interpreted as a free-rider strategy, allowing individuals to save the cost of producing and maintaining their own floral displays while still benefiting from pollinators attracted by neighbors' flowers.

Conclusions: Our findings indicate that the observed tendency for plants to produce larger floral displays when growing with kin, compared to non-kin, may arise from three distinct mechanisms: (1) altruistic behavior toward kin, (2) free-rider strategies toward non-kin, or (3) a combination of both. Thus, differences in floral traits between kin and non-kin alone do not provide conclusive evidence of altruism. Interpretation requires consideration of ecological and evolutionary contexts.

This research has been published in the *Journal of Evolutionary Biology*:

Tomizuka, H., Yamawo, A., & Tachiki, Y. (2025). Altruism or selfishness: Floral behavior based on genetic relatedness with neighboring plants. *Journal of Evolutionary Biology*, voaf015. <https://doi.org/10.1093/jeb/voaf015>

Butterfly counter-adaptations against multiple plant defences: arms race, plasticity-first and convergent evolution

Pinheiro De Castro E¹, Chowdhury R¹, Cicconardi F², Federle W¹, Montgomery S², Bak S³, Jiggins C¹

¹University of Cambridge, ²University of Bristol, ³University of Copenhagen

POSTER SESSION 1 - **P01.233**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The toxic and colourful butterflies of the Heliconiini tribe (~80 species) sequester cyanogenic glucosides from their obligatory Passiflora hostplants. To escape Heliconiini herbivory, some Passiflora species have disabled sequestration by diversifying their cyanogen structure, whereas others have invested in physical defences, such as hooked trichomes

Using larval performance assays, I have demonstrated that Heliconiini butterflies increase de novo biosynthesis of cyanogens, when compounds for sequestration are not present in their Passiflora hosts. This biochemical plasticity allows them to keep their toxicity despite the cyanogen profile of their hostplant. Using target-metabolomics data of over 700 Heliconiini butterflies from different populations, we performed ancestral state reconstruction analysis to show that biochemical plasticity was ancestral in this tribe, but has been lost in multiple lineages. We also used CRISPR to characterize the genes involved in cyanogen biosynthesis in Heliconiini (CYP405 AND CYP332). These genes are incomplete in sapho clade which is specialized in sequestration and might have lost biochemical plasticity. This therefore

represents an example of 'plasticity-first' evolution, whereby plasticity has enabled colonisation of a diversity of hostplants and then been lost as species specialise ecologically. Interestingly, Heliconiini butterflies and Zygaena moths, which also feed on cyanogenic plants, have independently coopted the same cytochrome P450s into cyanogen biosynthesis.

Moreover, we also have found phenotypic plasticity in the Heliconiini counter-adaptations to plant physical defences. We have shown that the hooked trichomes found in some Passiflora species are effective against most Heliconiini caterpillar due to its sharpness and unique elemental composition. Among other heliconiines, Heliconius charithonia is the only one that has overcome this physical defences by evolving a thicker cuticle and a more sclerotized gut. While their external counter-adaptation is constitutive, their internal counter-adaptation is inducible and have high fitness costs.

Our results emphasize the importance of phenotypic plasticity for coevolution and exemplify how plasticity can contribute to diversification. It also brings new knowledge on a text-book example of coevolution

Community tipping driven by predator-prey role reversal in a fishing-induced trophic cascade

Bharath D^{1,2}, Chaparro Pedraza C¹

¹Swiss Federal Institute of Aquatic Science and Technology (EAWAG), ²Institute of Ecology and Evolution, University of Bern

POSTER SESSION 1 - P01.215, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Top predators worldwide have experienced dramatic declines due to anthropogenic pressures such as overexploitation and habitat loss. Such catastrophic population collapses often trigger trophic cascades where mid-sized predatory species increase in abundance – a phenomenon known as mesopredator release. This may increase interspecific competition for resources or even reverse traditional predator–prey relationships, where mesopredators intensively prey on the early life stages of top predators, suppressing recruitment and potentially hindering population recovery. These drastic changes in community composition are thought to represent transitions between distinct, stable configurations of the system, known as alternative stable states. Such transitions or “regime shifts” typically occur when the system crosses critical thresholds, referred to as “tipping points”. In addition, human-induced stressors may trigger evolutionary responses in top predators, as indicated by the rapid changes in phenotypic traits of wild fish populations such as the size at maturation and reproductive investment, due to overharvesting. However, while these ecological and evolutionary changes often occur simultaneously, their joint dynamics and interactive effects on communities are poorly understood. To address this gap, we

build a multispecies ecological model with population structure, size- and food-dependent consumer growth and size-selective predation mortality. The food chain model consists of a size-structured predator that forages on a size-structured consumer, which, in turn, feeds on an unstructured basal resource. We investigate the effects of predator-prey role reversal on tipping in this system by varying the dietary preference of the adult mesopredator between the resource and the juvenile top predator. Additionally, we explore whether the rapid evolution and/or phenotypic plasticity of relevant life-history traits of the top predator, and their interaction, affect the risk, timing, and abruptness of regime shifts under various scenarios of fishing mortality. We formulate distinct model variants based on two trophic networks where the top predators have been heavily exploited: the Atlantic cod and the northern pike in the Baltic Sea, and parameterise the models using existing metabolic and life history data. We demonstrate that the eco-evolutionary dynamics of a fundamental biotic interaction under global change can drive regime shifts with dramatic consequences for trophic dynamics, community structure, and ecosystem functioning.

Divergent Defence: Multiple Evolutionary Routes of Algal Resistance and Their Costs

De Alwis P¹, Lievens E¹

¹Aquatic Ecology and Evolution Group, University of Konstanz

POSTER SESSION 1 - P01.223, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The evolution of host resistance initiates coevolution between hosts and parasites, thereby profoundly shaping both host communities and ecosystem structure. It is an important aspect that hosts can develop multiple resistance mechanisms to combat specific parasites. If different resistance mechanisms target different stages of infection, this could affect the further course of coevolution. Moreover, different defences may come with different costs, affecting host life-history traits and population dynamics. This study uses an alga-virus model system to investigate divergent host evolution, which could influence the subsequent course of host-parasite coevolution. In our previous work with the green alga *Chlorella variabilis* and virus PBCV-1, we generated a panel of 22 resistant algal clones that independently evolved resistance to the virus. Preliminary data suggest that these resistant clones can

have at least three distinct resistance mechanisms. Here, we will present the first data assessing whether the resistant *Chlorella* clones have different resistance mechanisms. Specifically, we will test whether algal clones show resistance by blocking different stages in the virus cycle: virus adsorption to the algal cell, depolarization and subsequent genome entry, or the release of progeny virions. Furthermore, we will investigate whether the initial cost of achieving this resistance varies among the resistant algal clones. This work will be the first information on diverse resistance pathways of *Chlorella* algae and lays the groundwork for understanding how variation in host resistance mechanisms can influence the evolution of hosts and parasites.

Ecological aspects of coinfections: Do laboratory experiments of within-host parasite interactions reflect the reality of coinfections in nature?

Ben-ami F¹, Halle S¹

¹Tel Aviv University

POSTER SESSION 1 - P01.227, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: In nature, organisms are commonly found to be infected by more than one parasite species, and many studies have demonstrated that parasites interact with each other in various ways, affecting each other's fitness within and between hosts. Yet our knowledge is mostly about interactions within individual hosts and their parasites, and our understanding of the role coinfections have at other scales (e.g., host populations and parasite communities) is far from being conclusive. More precisely, do laboratory experiments of within-host parasite interactions reflect the reality of coinfections in nature?

Materials and methods: We used the *Daphnia*-microparasites system to ask if within-host interactions among parasites cascade to patterns at the host population scale. To this end, we first studied in detail the interactions between the fungus *Metschnikowia bicuspidata* and the microsporidium *Hamiltosporidium tvaerminnensis* within individual *Daphnia magna*. Then, we studied the same combination of parasites in microcosm host

populations and asked if within-host interactions manifest themselves in the prevalence and density patterns of the parasites and the host. Finally, we studied the temporal dynamics of coinfections in natural host populations and asked whether the prevalence of coinfections, in general and of different members of the parasite community, hints on the, usually negative, interactions among coinfecting *D. magna* parasites.

Results: While within-host interactions indicated strong competition between the two species, with negative consequences for the host, their reflection in the microcosms patterns was weak. Furthermore, in natural populations coinfections were completely random and reflected the diversity of the community of parasites.

Conclusions: While the importance of coinfections is large at the individual scale, it decreases at more complex scales, where they are potentially diminished by other factors as well as by stochasticity.

Ecological conditions can promote female-biased sex-ratios: a case study in haplodiploid gregarious pine sawfly

Lindstedt C¹

¹University of Helsinki

POSTER SESSION 1 - **P01.207**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Ecological conditions can result in variation in selection pressure for mothers to produce the more helpful sex (i.e. local resource enhancement hypothesis). We tested this hypothesis with the gregarious pine sawflies (Hymenoptera), which rely on cooperative chemical defence in larval stage. Contributing to the defence is costly for an individual and individual's survival is expected to be higher in groups where a larger proportion of larvae produces the defensive secretion. Our data from wild populations show that sex-ratios in larval groups can vary from all-male to all-females. However, on average sex-ratios are female-biased both on group and population level. To study the benefits of having females in the larval group, we quantified the fitness and cooperative behaviour of individuals in virgin produced all-male groups and sexually produced mixed sex groups under low resin (control) and high resin content (harsh

environment) host plant diets (*Pinus sylvestris*). We also tested whether reproductive output differs between virgin and mated females. We found that cooperativeness was sex-biased: haploid male larvae contributed less to the group defence than females. Interestingly, males benefitted from the presence of their sisters especially in harsher conditions as males grew faster on a high resin diet in mixed-sex groups in comparison to all-male groups. In addition, we found that reproductive output was higher in mated than in virgin females suggesting that mating increased fertility of females. Altogether, these results suggest that local resource enhancement together with the benefits of sexual reproduction may promote female-biased sex-ratios. The role of the social structure of the group in the invasion success of gregarious herbivorous insects will be discussed.

Enhancing plant disease resistance through intra and interspecific diversification

POSTER SESSION 1 - P01.211, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Agricultural intensification has led to a significant reduction in cultivated biodiversity, with global food production increasingly dependent on a limited number of species. This trend has contributed to climate change, biodiversity loss, and human health concerns. One major consequence of crop genetic homogenization is the increased vulnerability of agricultural systems to pests, diseases, and weeds at both field and landscape levels. In contrast, diversification has emerged as a promising strategy for sustainable, pesticide-free agriculture by enhancing resilience and stability. At the national scale, diversification broadens crop variety, while at the farm level, techniques such as extended crop rotations, cover cropping, intercropping, and cultivar mixtures improve pest and disease control.

The French collaborative project MoBiDiv explores the role of diversification in influencing the establishment and evolution of plant diseases, pests, and weeds. Specifically, we aim to assess how diversification enhances the durability of disease resistance and alters disease susceptibility within mixed cropping systems. Additionally, we seek to determine whether intra-plot diversification drives genetic co-selection between interacting plants.

To evaluate the impact of intercropping on fungal disease incidence, we conducted field trials using three intercropping systems: (i) wheat-alfalfa, (ii) wheat-perennial prairie, and (iii) wheat-pea. Disease assessments focused on key fungal pathogens, including septoria tritici blotch and brown rust in wheat, and ascochyta blight and anthracnosis in pea.

Our findings demonstrated that intercropping effectively reduced disease severity, particularly in anthracnosis affecting pea. However, no significant effect was observed on wheat fungal diseases in the wheat-pea system, while septoria incidence was lower in wheat intercropped with prairie. This highlights the potential of certain intercropping combinations in mitigating specific disease pressures.

To further investigate the genetic mechanisms underlying these effects, we analyzed potential co-selection between plants that might influence susceptibility to fungal diseases in wheat intraspecific mixtures. We conducted the first co-Genome Wide Association Study (co-GWAS) between two interacting plants and tested whether loci involved in inter-individual interactions exhibited signatures of selection. We calculated Tajima's D values to detect selection traces, expecting co-selected loci to show more negative values than control regions. Linkage disequilibrium (LD) was also assessed between interacting loci, hypothesizing that co-selected regions would exhibit high r^2 values. Finally, we compared intra- and inter-subgenome interactions, postulating that co-selection would primarily occur within sub-genomes in ancestral wheat lines predating polyploidization. Our analyses did not detect clear evidence of co-selection. This suggests that intra-plot diversification influences disease suppression primarily through eco-physiological mechanisms rather than co-evolutionary genetic adaptation. Understanding the impact of these underlying mechanisms on disease reduction is important to optimize diversification strategies and resistance management.

Evolution of coexistence ability in experimental *Daphnia* mesocosms

Borgmann S¹, Becks L², Pantel J³

¹University Of Duisburg Essen, ²University of Konstanz, ³Université de Franche-Comté | Laboratoire Chrono-environnement

POSTER SESSION 1 - P01.217, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Understanding species coexistence is central to community ecology, given its role in biodiversity maintenance. Theory indicates that coexistence is determined by niche and fitness differences, i.e. differential resource use or other stabilizing mechanisms and relative competitive abilities of species. Both of these can evolve as a result of selection in underlying quantitative traits, and thus potentially alter coexistence dynamics. However, it remains unclear how adaptations to competitors develop over time and how abiotic environmental properties influence dynamics, shaping evolutionary trajectories of competition and coexistence. We conducted a multi-year, semi-natural outdoor mesocosm experiment with planktonic communities to study different selection pressures as drivers for evolution of coexistence. The mesocosms used realistic annual hydroperiods, which better allows us to determine whether rapid evolution observed within a growing season persists when genetic drift and sexual reproduction are considered, and also allows for eco-evolutionary feedback dynamics between phytoplankton and zooplankton. To generate distinct evolutionary histories, focal zooplankton species *Daphnia magna* and *Daphnia pulex*

were included either in monoculture or in competition into mesocosms as initially diverse populations (22 unique clones). Three years after the initial implementation, we tested how evolution acted on niche and fitness differences of focal *Daphnia* species.

Niche and fitness differences were measured in laboratory experiments, using recent methodology that recommends measuring distinct intrinsic, invasion, and no-niche (when niches are equivalent between the two species) growth rates. We hypothesized that *Daphnia* from competition treatments would evolve either increased niche differentiation and/or reduced fitness differences in competition treatments, facilitating coexistence by reducing direct competition or stabilizing effects. Our results showed evidence for reduction of fitness differences among *Daphnia* populations with histories of coexistence, but no consistent directional shifts in niche differences were observed. These findings indicate that *Daphnia* evolve mechanisms that impact coexistence in different, repeatable directions when the competitors are present or absent, and a next critical step will be to determine which life history traits drive the reduced fitness inequalities observed in populations exposed to competition.

Evolution of plasticity and character displacement in a fluctuating environment

Chevin L¹, Chauhan L¹

¹CEFE – CNRS

*POSTER SESSION 1 - **P01.193**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Species that compete for the same resource may undergo ecological character displacement (CD), where the phenotype of each species evolves to deviate from its optimum in the absence of a competitor, thus reducing the intensity of competition. As natural habitats are rarely static, interspecific competition is likely to occur in environments that fluctuate over time. Such environmental fluctuations can in turn cause the evolution of phenotypic plasticity for traits mediating the competition. However, the interplay of environmental fluctuations, evolution of plasticity, and character displacement, has been little investigated. We use a quantitative genetic model to study theoretically how a randomly fluctuating environment and evolution of plasticity influence the outcome of ecological CD between two competing species. We show that environmental fluctuations make the

conditions for CD more stringent, requiring stronger competitive selection relative to stabilizing selection. This occurs because environmental fluctuations reduces the average population size, and thereby competition intensity. Evolving plasticity can restore CD by buffering the impact of environmental fluctuations through phenotypic tracking, to a degree that depends on environmental predictability. Somewhat paradoxically, competition that favors phenotypic divergence among species can cause convergence in plasticity, when this reduces the load caused by fluctuations in phenotypic divergence. Our results shed light on how competition and plasticity influences evolution of the fundamental niche in a fluctuating environment.

Examining the relationship between genomic variation and avian cholera survival in an Arctic sea duck

Kroeze S¹, Burguete-Innocente E¹, Gilchrist G², Love O³, Forbes M⁴, Friesen V¹

¹Queen's University, ²Environment and Climate Change Canada, ³University of Windsor, ⁴Carleton University

POSTER SESSION 1 - P01.209, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Conservation efforts are urgently needed for Arctic species, as climate change allows diseases to spread farther north. However, critical information on the genetics of disease resistance is lacking. The Common Eider (*Somateria mollissima*) is an Arctic sea duck and is an important source of fresh protein and clothing insulation for northern and coastal communities. In 2006, avian cholera killed > 30 % of female nesting eiders at the largest breeding colony in the eastern Arctic (Mitivik Island, Nunavut, Canada).

Materials and methods: We are using whole genome sequencing and cutting-edge bioinformatic approaches to test for a genetic basis for resistance to cholera in eiders, utilizing an extensively archived time-series of DNA from the Mitivik Island colony to compare variation before and after the cholera epizootic. Using these whole genome sequences, we identified single nucleotide polymorphisms (SNPs) at genes previously found to be involved in immunity in other species. We tested whether this variation was associated with inter-individual variation in the eiders' mortality from cholera.

Results: We found that diversity of genes previously found to be involved in immunity (e.g., toll-like receptors or TLRs) was related to eider survival during the cholera epizootic. For example, heterozygosity at two genes, TLR5 and TLR3, was related to whether eiders

that were exposed to cholera survived. Additionally, we identified specific immune gene SNPs that were associated with eider survival during the cholera epizootic and found evidence of selection on SNPs in these genes. Specifically, several SNPs in TLR2B and TLR21 were also associated with disease survival. Considering only non-synonymous SNPs changed the results: heterozygosity at TLRs 2B, 3, 7, and 21 was associated with eider cholera survival. Additionally, several SNPs in TLR2B and TLR21 were associated with eider cholera survival.

Conclusions: These results suggest that immune gene variation affects resistance of wild Common Eiders to avian cholera. Additionally, we found that considering only nonsynonymous SNPs identified different genes putatively involved in disease immunity compared to considering all SNPs. One potential explanation is that synonymous variation may have masked the role of nonsynonymous variation. This highlights the importance of considering functional genetic variability separately from total genetic variation. Our work adds to a small but growing body of literature regarding the population genetics of disease resistance in wild populations. Our findings inform the genomic impacts of emerging infectious diseases and the potential for species adaptation, and therefore the vulnerability of Common Eiders and Arctic species in general to emerging pathogens.

Experimental Removal of Niche Construction Alters the Pace and Mechanisms of Resistance Evolution

Lo L^{1,2}, Schulz N¹, Korša A¹, Jensen H¹, Friedrichs J³, Müller C³, **Kurtz J**¹

¹University of Münster, ²Max Planck Institute for Chemical Ecology, ³Bielefeld University

POSTER SESSION 1 - P01.196, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biotic interactions can strongly depend on ecological conditions. In turn, ecological conditions can be influenced by the biotic interaction partners themselves. Specifically, niche construction is a central eco-evolutionary process in which organisms modify their environment. Such modifications have the potential to profoundly affect hosts and their biotic interaction partners. However, experimental knowledge how niche construction affects the evolution of biotic interactions is currently lacking.

Red flour beetles modify their environment by releasing quinone-rich stink gland secretions, a form of external immunity. We tested in an evolution experiment how experimental removal of niche construction—using RNAi of a key gene needed to produce stink gland secretions—affects the beetles' adaptation to the bacterial entomopathogen *Bacillus thuringiensis*. In each generation, beetles inhabited conditioned flour either with

regular or drastically reduced stink gland secretion content. Compared to the non-exposed control, all bacteria-exposed regimes rapidly evolved bacterial resistance within only six generations. However, beetles evolving with intact niche construction acquired resistance as soon as after three generations, indicating that adaptation was initially facilitated by niche construction. RNAseq of evolved beetles showed that gene expression differed strongly between the selection regimes, revealing that the mechanisms underlying resistance were dependent on niche construction.

After another nine generations of experimental evolution, we further analysed whether larvae-associated microbiota or the beetles' secretions had changed and found that lines evolving with the possibility to construct their niches showed increased microbial diversification. In sum, our findings provide much-needed empirical evidence on the role of niche construction for resistance evolution and its potential genetic basis.

Exploring Density-Dependent Shifts in Symbiotic Interactions Using *Paramecium bursaria* and *Chlorella* Species

Chu L¹, Horas E², Becks L¹, Sathe S¹

¹University of Konstanz, ²Universidad Politécnica de Madrid

POSTER SESSION 1 - P01.214, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The endosymbiosis between ciliate hosts and endosymbiotic algae have evolved independently several times. These relationships are often nutrient mutualisms, where ciliates provide nitrogen to the algae and the algae provide carbon to the ciliates, resulting in a net positive effect for both partners. However, the net effect of the interaction can shift depending on environmental conditions, although little is known about when and why these shifts occur. In our study, we investigate when the balance of costs and benefits of one or both symbiosis partner shifts so that the net effect on each partner changes from positive to negative or vice versa. We use *Paramecium bursaria* as a host and test its interactions with several closely related green algae of the genus *Chlorella*, most of which are capable of forming facultative endosymbiotic relationships with the ciliate. By measuring how costs and benefits vary under different environmental conditions,

such as changes in light, nutrient availability, and host and symbiont densities, we assess the context-dependence of the symbiosis. Our results show that as *P. bursaria* density increases, the net effect of the endosymbiotic relationship often shifts from positive to negative, and this shift depends on the specific *Chlorella* species involved. By teasing apart how costs and benefits respond to changing conditions, we begin to understand why these relationships change and what this means for stability of the symbiosis. Overall, our results suggest that the relationship between *P. bursaria* and *Chlorella* species can range from mutualism to exploitation, depending on environmental factors and the identity of the algal partner. Understanding how these conditions shape the dynamics of endosymbiosis will provide important insights into its ecological role and how such interactions evolve and persist over time.

Exploring the evolutionary dynamics of mating system shifts and speciation in *Capsella*

Orsucci M^{1,4}, Sartori K¹, **Lombardi A**¹, Vanikiotis T², Ouvrard P¹, Wärdig C¹, Messer M³, Köhler C³, Sicard A¹
¹SLU - Swedish University of Agricultural Sciences, ²University of Ioannina, ³Max-Planck-Institut für Molekulare Pflanzenphysiologie, ⁴Stockholm University

POSTER SESSION 1 - **P01.221**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Most flowering plants are obligatory outcrossers, which means that they rely on pollen vectors for reproduction. This type of reproduction entails a self-incompatibility system that prevents inbreeding. Repeatedly in plant evolution this system broke down allowing reproduction through self-fertilization. This transition from outbreeding to selfing often leads to significant morphological and functional changes, including reduced flower size, altered sex allocation, and a decreased distance between anthers and stigma. These convergent phenotypical traits are known as the selfing syndrome. Selfing species also become quickly isolated from their outbreeding ancestors, but it remains unclear what genetic and ecological mechanisms reinforce isolation between newly evolved selfers and their outcrossing progenitors.

To address this, we focused on the *Capsella* genus (Brassicaceae) which emerged as an ideal model for studying the transition from outbreeding to selfing. In this study, we investigated how the incipient selfing lineage *Capsella rubella* (Cr) (50,000 years ago) became reproductively isolated from its outcrosser ancestor *Capsella grandiflora* (Cg).

We investigated how different barriers to gene flow affect reproductive isolation. After a survey to find populations that live in sympatry, we discovered that hybrid formation is possible in nature but limited. Interestingly, the number of hybrids mothered by Cr plants is higher than the ones in Cg plants. This directional gene flow was further confirmed by admixture analysis, in which we observe higher introgression rates from Cg to Cr but lower in the opposite direction.

Hybrid disgenesis caused by the developmental failure of interspecific seed nutritive tissues is prominent between the two species. Such defects in seed formation are attributed to

differences in the intensity of parental conflicts between outcrossing and selfing lineages, itself driven by variation in intrasexual competition. This result suggests that the low hybridization rate could trigger reproductive interference, thereby promoting isolation before fecundation. Pre-zygotic barriers are more effective in preventing resource waste derived from reproductive interference, as they prevent fertilization and, hence, gene flow. Flowering phenology is mostly overlapping, but characteristics related to pollinators' attraction limit cross-pollination. In fact, we observe the typical flower morphology associated with the selfing syndrome in Cr: reduction in flower size, pollen number, volatile production, limited pollinator visits and gene flow. In particular, the striking difference in pollen number, higher in Cg and lower in Cr, greatly limits the possibility of Cr pollen to reach Cg pistils. However, the higher Cg pollen production, due to high male competitiveness, increases the possibility of pollination of Cr. Such promotion of interspecific directional gene flow, likely explain higher hybrid mothering by Cr and introgression rate from Cg to Cr. In Cr, early self-pollination nevertheless significantly reduces interference from Cg pollen.

Lastly, post-pollination prezygotic barriers, like pollen compatibility and efficiency, seem to be relatively weaker. Nonetheless, we observe partial germination of interspecific pollen on both pistils. Cg pollen outcompetes Cr pollen in fertilizing ovules, suggesting a difference in pollen tube growth, probably due to enhanced male competitiveness in outcrossers.

Our work clarifies how the interplay of different selective pressures shapes barriers to gene flow between lineages with contrasting mating systems.

From antagonists to mutualists: the emergence of brood-site pollination in Ochyromerini weevils revealed by a new weevil specific UCE probe set.

Zelvelder B¹, Haran J³, Benoît L³, Loiseau A², Kergoat G², Allio R²

¹Université De Montpellier, ²INRAE, ³CIRAD

POSTER SESSION 1 - P01.212, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

As phytophagous insects, weevils (Coleoptera, Curculionoidea) are mostly known for their antagonistic relationships with plants. Yet, examples of mutualistic interactions between weevils and plants are being revealed by a growing number of publications. Recent research showed that transitions from antagonism to mutualism emerged at least a dozen times in the evolutionary history of weevils in the form of brood-site pollination. Each of these evolutionary events makes up an ideal repeated pattern to study the emergence of mutualistic interactions. In this context, a robust phylogenetic background for weevils is necessary. Thankfully, the insect tree of life is being continuously pushed forward thanks to the widespread use of ultraconserved elements for phylogenomic analyses. However, despite previous efforts, the evolutionary history of weevils, has yet to be confidently resolved due to insufficient phylogenetic signal in currently available probe sets. To solve this issue, we designed a new set of probes specific to Curculionoidea with a novel method based

on genomes alignment. Genetic markers obtained with this method offer better phylogenetic support at wide and shallow taxonomic levels than single reference based methods commonly used today. Using this new set of UCE, we took advantage of museum specimens to reconstruct the first phylogenetic tree of one major and broadly understudied group of brood-site pollinating weevils: the Ochyromerini tribe. Combined with what we know of their ecological interactions, these results shed light on the systematics of the tribe and the pattern of emergence of mutualism at the species scale. Ongoing research will focus on many other aspects of their evolutionary history, such as their biogeography, diversification rates and host plant associations dynamics. While we are planning to do the same with other pollinating weevil lineages, we hope that sharing this new set of Curculionoidea baits along with the methods utilized to generate and analyse them will allow to unveil the deeper radiation of the most diverse group of insects known so far.

From spore to infection: How the intensity and frequency of heatwaves shape bacterial infections of a crustacean

Shehady M¹, Ben-ami F²

¹Tel-aviv University, ²Tel-Aviv University

POSTER SESSION 1 - P01.200, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Host-parasite interactions are key components of ecosystems, yet their dynamics are increasingly shaped by climate extremes such as heatwaves and drought. While elevated temperatures are known to affect infection traits in both hosts and parasites, little is known about how climate stress impacts parasites during their off-host stages. We investigated how heat exposure affects the free-living spores of the bacterial parasite *Pasteuria ramosa*, which infects the freshwater crustacean *Daphnia magna*. Spores were subjected to a range of elevated temperatures (20-60°C) and durations (1-21

days), simulating realistic heatwave conditions, then used in infection assays. Surprisingly, heat-treated spores retained their ability to attach to hosts, but failed to complete infection—indicating that thermal damage occurs after attachment, disrupting later stages of the parasite's development. These findings reveal a hidden vulnerability in parasite life cycles and underscore the need to incorporate off-host stages into predictions of disease dynamics under climate change.

Host-parasite coevolution in complex natural systems: linking immune gene variation to infection patterns across amphibian species

Cetin C¹, Babik W¹, Megía-Palma R², Pabijan M¹, Dudek K¹, **Palomar Garcia G**^{1,2}

¹Jagiellonian University, ²Complutense University of Madrid

POSTER SESSION 1 - P01.222, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The importance of coinfection in host-parasite coevolution is poorly understood, especially for non-model organisms and complex natural systems (i.e. multihost-multiparasite). This knowledge is urgently needed for endangered taxa such as amphibians, since infectious diseases play a major role in their dramatic decline. Immune gene variation, particularly in the major histocompatibility complex (MHC), offers a powerful tool to explore the evolutionary dynamics between hosts and their parasites, as it reflects selective pressures imposed by infections. In this study, we adopt a multi-scale framework combining MHC class I and II genotyping from over 1000 individuals across 20 European amphibian species with

infection data for seven parasite taxa. Using generalized linear mixed models and phylogenetically informed analyses, we investigate associations between immune gene diversity at both individual (infection status and parasite load) and population scales (prevalence and load). By embracing the ecological complexity of multihost-multiparasite networks, our integrative approach offers new insights into host-parasite coevolution in natural ecosystems. To our knowledge, this is the first study to apply such an approach to amphibian populations, providing a crucial step toward understanding and mitigating their ongoing biodiversity loss.

Is a generalist parasitic plant locally adapted to its plant hosts?

Doherty G^{1,2}

¹University Of Edinburgh, ²Royal Botanic Garden Edinburgh

*POSTER SESSION 1 - **P01.203**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Parasitism has a major role in the evolutionary process, often resulting in speciation and diversification. Parasitic plants range from generalists with many diverse plant hosts to specialists with narrow host ranges. However, it is uncertain whether generalist parasitic plants have preferences for local hosts that have been overlooked in previous field observations and growth experiments. To test for this local adaptation, seeds of a semi-parasitic *Euphrasia* (Orobanchaceae) and three of its common grassland hosts were collected across a wide spatial scale. A common

garden experiment, using thousands of pots, compared fitness and survival across sympatric and allopatric parasite-host combinations. Parasite performance was largely unaffected by host sympatry, suggesting no local adaptation to host populations. However, genetic variation existed between parasite populations in traits such as flower size, and broad preferences for host species were seen. Overall, this project explores the maintenance of a generalist strategy despite potential pressures to adapt to local hosts in these co-evolutionary relationships.

Local adaptation of host-parasite coevolution on spatial networks

Naik S¹, Fronhofer E¹

¹ISEM

POSTER SESSION 1 - **P01.195**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Parasites are key components of ecosystems, yet their distribution and diversity across landscapes remain poorly understood. Parasite diversity hot- and cold-spots arise from complex interactions between host populations, ecosystem variables, and environmental changes. To understand coexistence of parasites, we need to understand coexistence of specialist to generalist strategies that is driven by niche breadth evolution in parasites. A key challenge is linking ecological and evolutionary dynamics to the emergence of different properties of modularity or nestedness in host-parasite interaction networks. In this study, we develop a spatially explicit, individual-based simulation model to explore how selection regimes, dispersal, and landscape connectivity shape the emergence and maintenance of parasite diversity and network structure.

Our model considers a gene-for-gene (GFG) framework for infection, incorporating fitness trade-offs associated with resistance and infectivity, as well as virulence-transmission trade-offs. Presence of trade-offs would lead to fluctuating selection dynamics, and without costs would lead to arms race dynamics. We simulate two

landscape structures: Optimal Channel Networks (OCNs), representing aquatic ecosystems, and Random Geometric Graphs (RGGs), representing terrestrial ecosystems. We predict that under fluctuating selection, spatial heterogeneity in adaptation maintains high genetic diversity and drives the formation of modular infection networks, particularly in peripheral or poorly connected patches. In contrast, arms race dynamics lead to directional selection, reduced diversity, and the evolution of nested network structures dominated by generalist parasite genotypes. Landscape topology and the evolution of dispersal behaviors strongly influence these outcomes, modulating the spatial scale of coevolution. Dispersal evolves within a spatial network, allowing us to explore the coevolution of movement strategies and local adaptation.

Our results offer mechanistic insights into how coevolutionary dynamics and landscape structure interact to shape host-parasite networks. By identifying the conditions under which modularity or nestedness arises, this work provides a theoretical foundation for predicting parasite diversity patterns and managing disease risk in complex, changing ecosystems.

Making sense of floral scents: species- and population-level variation in floral scent in *Mimulus* section *Erythranthe* and its evolutionary significance

Byers K¹, Neequaye M¹, Wenzell K^{1,2,3,4}, Asare B¹, Kennedy E¹

¹John Innes Centre, ²South Dakota State University, ³California Academy of Sciences, ⁴University of Maryland

POSTER SESSION 1 - **P01.202**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Floral diversity is immense, with nearly 300,000 species of angiosperms described to date. The number of phylogenetically diverse floral species that share common characteristics implies a background pattern of selection acting on floral traits. Unique combinations of these floral traits are hypothesized to reflect selective pressure imposed by certain classes of pollinators. One flower character in particular, scent, has been hypothesized to operate as an unseen signal to attract certain pollinators, particularly when combined with other signals such as color and shape. However, the contribution of scent in pollinator-mediated selection between sister taxa has nearly always been inferred and rarely directly tested, and pollinator sensory mechanisms that drive attraction often remain unclear. The genus *Mimulus* (Phrymaceae) forms a developing model system for studying floral diversity and pollinator-driven speciation using a combination of genetic tools and field ecology. However, the level of floral trait diversity between populations of *Mimulus* section *Erythranthe* has been poorly studied, and most studies have focused on only single inbred lines.

Section *Erythranthe* contains 7-9 species (depending on definition) with potentially

independent transitions from ancestral bee pollination to derived hummingbird pollination, making it an ideal system to study pollinator transitions and population-level variation of floral traits. Populations and species within section *Erythranthe* cluster by floral scent profile despite broad overlap in the volatiles produced, and there is substantial population-level as well as species-level variation in individual floral scent compounds. Surprisingly, the selfing species *M. parishii* produces the most diverse array of floral volatiles of any of the 5 most widespread species. Volatiles across 5 populations of the hummingbird-pollinated *M. cardinalis* differ significantly by population, with qualitative and quantitative floral scent variation normally only seen at the species level. Expression and function of floral scent genes also varies across the section. I will present these results and others from section *Erythranthe* and discuss their implications for species- versus population-level variation, chemotaxonomy, pollinator guild use, ancestral states of floral volatiles, and the role of specific volatiles in biotic interactions. Floral scent may provide a mechanism for diversification and pollinator adaptation in angiosperm taxa, but more studies are needed at multiple taxonomic levels to truly unpack its importance in these processes.

Neuropeptides mediate behavioral and lifespan changes in cestode-infected ants

Blasi G¹, Schwolow K¹, Darras H¹, Foitzik S¹

¹Institute of Organismic and Molecular Evolution, Johannes Gutenberg University

POSTER SESSION 1 - **P01.208**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Parasites have evolved strategies to manipulate host behavior to increase their fitness, particularly during intermediate stages of complex life cycles. As Dawkins proposed, such alterations may represent expressions of the parasite's extended phenotype: the host becomes a tool to enhance parasite transmission. Social insects show substantial behavioral variation associated with caste differentiation and division of labor. Neuropeptides—short-chain signaling molecules of 3-100 amino acids—are central regulators of these behaviors, influencing aggression, foraging, stress responses, and task specialization. Synthesized in neurons and acting via specific receptors, neuropeptides are likely targets for parasitic manipulation.

We investigated the role of neuropeptides in the cestode-induced behavioral shifts observed in the ant *Temnothorax nylanderi*, which serves as an intermediate host for the tapeworm *Anomotaenia brevis*. Ants become infected during the larval stage and, subsequently, exhibit extended lifespans and pronounced morphological and behavioral changes. Infected workers are largely inactive, stay near the brood, do not respond to nest disturbances, retain juvenile physiological characteristics, and receive increased care from nestmates. These queen-like traits may enhance predation risk by the definitive woodpecker host, promoting parasite transmission.

To examine the molecular basis of these alterations, we sequenced mRNA from brain and fat body tissues of uninfected workers, uninfected queens, and infected workers. We annotated 2 new neuropeptides—CAPA and an ITG-like peptide—and 17 G protein-coupled receptors in the *T. nylanderi* genome with high tissue-specific expression.

Whole-transcriptome analysis revealed that infected workers exhibit an expression profile intermediate between healthy workers and queens. In the brain, about two-thirds of the neuropeptides were downregulated in infected workers, and a distinct subset showed reduced expression in queens. In the fat body, half of the neuropeptides were similarly downregulated in both infected workers and queens, suggesting that these may be involved in their shared long-lived phenotype.

Interestingly, four neuropeptides with potential roles in the phenotype of infected ants—including low aggression, endocrine reprogramming, and increased desiccation resistance—showed altered expression, suggesting a molecular basis for the behavioral and physiological changes induced by the parasite. Tachykinin and Short Neuropeptide F—linked to aggression and locomotion, respectively—were strongly downregulated in infected worker brains compared to uninfected individuals and queens. Neuroparsin, shown to be a brain-derived juvenile hormone inhibitor in locusts, was upregulated in the fat body of infected ants. Inotocin, a vasopressin-like neuropeptide associated with desiccation resistance through regulation of cuticular hydrocarbon synthesis, was predominantly expressed in the fat body of infected individuals. In clonal raider ants, it further modulates social foraging behavior in an age- and context-dependent manner, contributing to behavioral individuality and the division of labor.

Our findings demonstrate that cestode infection systematically alters neuropeptide signaling in the worker host, partially resembling the profile observed in the long-lived queens. The consistent and specific suppression of neuropeptides in infected individuals, especially in the brain, suggests that this signaling pathway is a key mechanism by which parasites modulate host physiology and behavior to facilitate transmission.

Parasite population genomics sheds light on canid evolution

POSTER SESSION 1 - P01.201, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Dogs were the first animals domesticated by humans, making them a key focus in evolutionary genomics. While significant progress has been made in tracing the origins of domesticated dogs, the evolutionary histories of pre-domesticated canids and some contemporary wild canid populations, such as the Australian dingo, remain poorly resolved. One approach to help clarify the enigmatic histories of these canids is to analyse the genomes of their parasites. Parasites often share a deep co-evolutionary history with their hosts, and their genomes can serve as useful markers for inferring host origins, migration, and population structure. Since parasite genomes are typically smaller than those of their hosts, they can also be sequenced and analysed more efficiently, requiring less time, lower costs, and fewer computational resources. One of the most important parasites infecting canids is heartworm (*Dirofilaria immitis*), which causes significant morbidity and mortality worldwide. These parasites are widely believed to have dispersed globally with domesticated dogs in contemporary times; however, this hypothesis remains untested. This study aimed to use genome-wide analysis of heartworms to gain insights into the parasite's evolutionary history, as well as that of their canid hosts. **Materials and methods:** We conducted the largest population genomics study of heartworms to date, using whole-genome sequencing data for 127 modern specimens from four continents (Europe, North America, Australia, Asia). Most parasites were obtained from dogs, but some were collected from other hosts such as cats and foxes. The sequencing reads were mapped to a reference genome using a NextFlow mapping pipeline utilising Minimap2, GATK, Samtools, and Sambamba. Variants were identified using GATK and filtered based on various quality metrics. The population structure of the global heartworm dataset was explored using principal

component analysis (PCA), nucleotide diversity (π), absolute nucleotide divergence (DXY), genetic differentiation (FST), and linkage disequilibrium (LD). To assess admixture in the cohort, we analysed ancestry proportions with NGSadmix, produced maximum-likelihood trees using TreeMix, and calculated D-statistics with AdmixTools. Population demographics were investigated by estimating historical population sizes and divergence times of subpopulations using SMC++.

Results: We found distinct genetic differences between heartworms across continents, with divergences (~63 Kya) pre-dating the domestication of dogs (14–40 Kya). This indicates that heartworms have a much older origin and dispersal history than previously recognised, likely involving ancestral wolf or coyote hosts. Our parasite data supports the hypothesis of a once-connected ancient canid population in the Northern Hemisphere that was later fragmented by the formation of large continental ice sheets during glacial periods. These glacial events reduced host connectivity, leading to the deep continental splits we observe in their heartworm parasites today. We also found that Australian heartworms originated in Asia, which is consistent with the migration of dingoes from Asia to Australia thousands of years ago. Finally, the high genetic similarity we found between European and Central American heartworms likely reflects more recent dispersal via domesticated dogs following the colonisation of the Americas in the late 15th century.

Conclusions: Our findings indicate that heartworms have likely been parasitising canid hosts since ancient times, with major dispersal events associated with pre-domesticated canids, dingoes, and more recent domesticated dogs. Most importantly, our study demonstrates the utility of using parasites as markers for inferring the evolutionary history of their hosts.

Questioning the early Miocene origin of grass-feeding noctuids: evidence from a phylogenomic dataset

Nedumpally V¹, Õunap E^{1,2}, Barry Davis R¹, Tammaru T¹

¹University of Tartu, ²Estonian University of Life Sciences,

POSTER SESSION 1 - P01.229, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Recent studies have indicated that Miocene grassland expansion, driven by global cooling and declining atmospheric temperatures, played a significant role in the radiation of grass-feeding herbivore lineages. The large lepidopteran family Noctuidae, comprising numerous grass-feeding clades, provides a good target taxon for testing these hypotheses. A recently published time-calibrated phylogenetic tree based on a limited number of genetic markers suggested that diversification of the predominantly grass-feeding noctuid tribe Apameini started in the early Miocene, i.e. more than 22 million years ago, potentially coinciding with the expansion of grasslands. However, subsequent analyses using six genes in Sesamiina, a subtribe of Apameini, revealed contrasting macroevolutionary patterns within the insect–grassland system, raising questions about the extent to which grassland expansion influenced the evolution of grass-feeding herbivores. In the present study, we aimed to construct a time-calibrated phylogeny of the tribe Apameini using a large molecular dataset.

Materials and Methods: We first constructed a phylogenetic tree in IQ-Tree using 333 species (296 noctuids and 37 outgroup taxa), based on 548 protein-coding genes totaling 249,138 nucleotides. This tree was then used as a fixed topology for our time-calibrated analysis, which was conducted using a reduced dataset due to software limitations. The reduced data set comprised the 24 longest loci with at least 90% taxon coverage, totaling around 54,000bp. We used the five secondary calibration points taken from recent literature to date the tree in Beast 1.10.4. To detect diversification rate

heterogeneity across the tree, we employed the Bayesian Analysis of Macroevolutionary Mixtures (BAMM) software, version 2.5.0.

Results & Conclusion: The time-calibrated phylogeny inferred in this study indicates that the diversification of Apameini began approximately 8.66 million years ago, i.e. substantially more recently than in previous estimates. Likewise, the divergence between the lineages leading to *Busseola fusca* and *Sesamia nonagrioides* was estimated at around 6.14 million years ago in this study, contrasting with earlier estimates ranging from 18 to 22 million years. Several studies suggest that a major radiation of grasses occurred between 3–9 Mya, driven by environmental changes. Notably, our results place the diversification of Apameini precisely within this time window. Diversification rate analysis using BAMM indicates two instances of rapid radiation in Apameini. One of them, that took place approximately 2 to 5 Mya, involves the genus *Apamea*, which is characterized by larvae feeding largely on the roots of their foodplants. The other rapid radiation event associated with a lineage that comprises several rather diverse genera of the subtribe Apameina, was estimated to have taken place about 3 to 5.5 Mya. Our results prove that the diversification rate of Apameina increased during the period of grassland expansion, though views questioning this pattern had been published earlier. This study thus emphasizes that drastic changes in the Earth's climate can lead to a rapid increase in biodiversity, driven by the accelerated rate of adaptive radiation.

RangeShifter 4.0: modelling spatial eco-evolutionary dynamics for multiple interacting species

Pannetier T¹, Bocedi G¹

¹University Of Aberdeen

POSTER SESSION 1 - P01.219, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Mitigation of the current biodiversity crisis calls for the improvement of biological forecasts. Both evolution and species interactions have been highlighted as decisive factors determining species' responses to global change but are yet missing from most models projecting these responses. The formulation of accurate predictions is complicated by three factors. First, realistic interactions often involve more than two species. Second, climate change is expected to reshape interaction networks as range shifts bring previously isolated species into sympatry. Third, adaptation to new conditions is likely to alter the intensity or nature of species interactions.

Process-based models are valuable tools to tackle these challenges as they can explicitly integrate the processes underpinning eco-evolutionary dynamics, thus overcoming the limitations of the more popular correlative approaches. The spatially explicit, individual-based model RangeShifter has been used extensively to simulate the eco-evolutionary dynamics of single species, with applications ranging from studies of range expansion of invasive species to theoretical investigations of the interplay between the evolution of dispersal traits and environmental change.

Here, we introduce a new version of RangeShifter that extends the modelling platform to encompass any number of species. The interaction module generalises the Lotka-Volterra models of competition and predation to capture a wide range of interaction types in a single framework. Interactions are defined by a set of coefficients affecting demographic processes such as reproduction and survival. This architecture and the genetic module recently introduced in RangeShifter 3.0 provides the infrastructure to implement evolution of the traits controlling interactions, allowing them to shift along the antagonism-mutualism continuum as environmental conditions change.

Importantly, the flexible simulations enabled by RangeShifter 4.0 will facilitate the development of new theory, for example investigating evolution of species' interactions in changing environments in interplay with demographic and spatial processes, and other traits evolution (e.g. dispersal), and inform empirical applications tackling the interplay between environmental change, biotic interactions and species ranges, beyond single species systems.

Signatures of Reproductive Skew and Corresponding Multiple Merger Coalescence (MMC) in Populations of *Plasmodium falciparum*

Srinivasan U^{1,2}, Anderson M¹, Tellier A¹

¹Technical University of Munich, ²Johannes Gutenberg University

POSTER SESSION 1 - P01.216, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The Kingman coalescent model, which assumes sexual reproduction, discrete, non-overlapping generations, and low offspring variance, does not always apply to species with atypical life histories. One such atypical life history strategy is "sweepstakes reproduction," wherein organisms display considerable variance and skew in individual reproductive output due to complex life cycles and stochastically changing ecological factors, leading to multiple merger coalescent (MMC) genealogies. We hypothesise that *Plasmodium falciparum*, the protozoan malaria parasite, exhibits such reproductive skew and, by extension, MMC genealogies. Analysing genomic data from Southeast Asian *P. falciparum* populations, we observe signatures consistent with MMC: low genetic diversity and a U-shaped synonymous derived allele

frequency spectrum, both deviating from Wright-Fisher-Kingman expectations. Using Sequential Markovian Coalescent (SMC)-based approaches, we infer low to moderate values of the α parameter of the β -coalescent (MMC) model, indicating frequent and strong multiple merger coalescence across the genome. However, validation with biologically realistic simulations reveals that the method shows considerable variability and a slight downward bias in the inferred α estimates. These findings support the presence of MMC in *P. falciparum*, challenging the validity of traditional population genetic analyses, while also highlighting the need for further research to strengthen confidence in our insights into the strength and mechanisms driving MMC in this malarial parasite.

Syntopy promotes song divergence in a Neotropical avian radiation

García-Navas V¹, Martín del Campo A¹, Rodríguez-Rey M², Laiolo P³

*POSTER SESSION 1 - **P01.191**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Theory predicts that selection against maladaptive hybridization leads to divergence of sexual characters in co-occurring closely related species. Consequently, signal disparity should be greater between sympatric versus allopatric lineage pairs. However, this pattern may also result from species sorting or the greater evolutionary age of sympatric pairs. We used species pairs comparisons to examine the existence of acoustic divergence in a Neotropical montane radiation, the Rhinocryptidae, whose members tend to occupy different elevational ranges. Most rhinocryptids exhibit conservative morphology and are only differentiated by song attributes. Our results show that sympatric species pairs that overlap in elevation exhibited overall greater song divergence compared to

allopatric species pairs after controlling for morphological differences, age and phylogenetic effects. Song divergence decreased when excluding sympatric pairs that do not overlap in elevation, suggesting that selection for improved species identification between co-occurring (syntopic) species accentuates signal differentiation. Comparative evolutionary models of signal differentiation over time revealed a similar pattern which suggests that sexual selection in syntopy might have driven reproductive character displacement in this radiation. We conclude that selection against the production of unfit hybrids could favor acoustic traits that reliably signal species identity in tropical environments where many taxa are poorly differentiated by visual attributes.

The genomic basis of an obligate ant-plant symbioses

Bourne N¹, Campbell L², Walker-Hale N², Dunning L¹, Chomicki G²

¹University Of Sheffield, ²Durham University

*POSTER SESSION 1 - **P01.205**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Mutualisms are ubiquitous across taxa, playing a pivotal role in the evolution and functioning of life on earth. These interactions vary from loose, facultative interactions across many species to tight, one-to-one interactions on which species depend for survival or reproduction. How these interactions impact the genome evolution of interacting individuals has largely only been explored in endosymbionts with 'macro' mutualisms rarely studied. We address this question using the farming symbiosis between six species of *Squamellaria* plants and their obligately-specialised cultivator *Philidris nagasau*. This provides a great study system as three other *Squamellaria* species facultatively associate with up to 14 other species of arboreal ants allowing for direct comparisons. Additionally, the ant genus *Philidris* includes obligate, facultative and non-plant

mutualists thus this system offers a range of dependencies in both macro-mutualists. We Used high coverage PacBio Hifi, Hi-C and illumina sequence data to assemble, annotate and compare key genome characteristics between the obligate and facultative species and resolve their respective phylogenies. We then utilise comparative genomics to trace the evolution of interaction-related genes among obligate and facultative *Squamellaria*, *P. nagasau*, and other facultatively associating *Philidris* ant species, revealing dependency specific patterns in gene family evolution. Combined with existing ecological observations, these results reveal how mutualistic dependency influences genome evolution, establishing a foundation for understanding the genomic basis of complex, non-microbial mutualisms.

The INTERACT project: Understanding evolution of common bean plant-plant interactions

²Department of Biotechnology, University of Verona

POSTER SESSION 1 - P01.213, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Agroecosystems have undergone significant transformations due to crop domestication, modern breeding, and intensive agricultural practices. These changes have resulted in increased environmental control and reduced genetic diversity of cultivated stands, greatly simplifying abiotic and biotic interactions. Among biotic interactions, sustainable strategies based on positive plant-plant interactions should be promoted to address challenges posed by climate change. However, their genetic and molecular bases remain poorly understood, highlighting a critical knowledge gap that must be filled.

Within this framework, the INTERACT project aims to unravel key regulatory pathways involved in intraspecific plant-plant interactions by analyzing gene expression, metabolite profiles, and microbial communities across wild, landrace, and cultivated genotypes of common bean (*Phaseolus vulgaris*), grown in binary mixtures and pure stands. The species complex evolutionary history, shaped by two independent domestication events in geographically distinct gene pools (Mesoamerican and Andean), provides a unique replicated system for studying these mechanisms.

Materials and Methods: This study uses 18 common bean genotypes (9 for each of the Mesoamerican and Andean gene pool), representing the two stages of crop evolution (wild --> landraces; landraces --> cultivars), resulting in 3 wild, 3 landraces, and 3 modern cultivars for each gene pool. Genotypes were selected based on available genotypic data from previous projects (INCREASE, BEAN_ADAPT, BRESOV, NextBEAN), ensuring a wide range of genetic backgrounds.

The experiment was conceived to test 90 genotype combinations (including 18 pure stands) across both gene pools arranged in a complete randomized block design (CRBD) with three replicates. These include 45 combinations

per gene pool: 9 pure stands and 36 mixed pairs (wild-landrace, wild-cultivar, and landrace-cultivar). Pots were filled with a uniform soil mix from a local organic farm, vermiculite, and universal soil.

Two parallel experiments (destructive and non-destructive) have been performed in controlled environment. In the first one, root and leaf tissues have been collected after four weeks for RNA extraction (transcriptomics) and metabolomics analysis. Soil samples have been obtained for DNA extraction (metagenomics). For metabolomics and transcriptomics both pairs of the mixtures were sampled separately, while for metagenomics a composite sample of the two pairs was collected. The non-destructive experiment is currently ongoing; it is focused on seed production for metabolomics. Seeds will be also analyzed using a multispectral camera to capture images across multiple wavelengths.

Results: Expected results aim to identify differentially expressed genes associated with intraspecific plant-plant interactions. Metabolomic analysis will uncover changes in chemical signaling, while microbial community profiling will provide insights into how these interactions are influenced by soil microbiota. Comparative analyses between the Mesoamerican and Andean gene pools will assess the effects of domestication and breeding.

Conclusions: This integrative study will enhance our understanding of the agroecological genomics foundations of intraspecific interactions in common bean. By analyzing genes, transcripts, metabolites, and microbial communities, we will uncover how domestication and breeding have shaped plant communication mechanisms. The findings will contribute to plant breeding programs aimed at improving crop resilience, productivity, and sustainability by leveraging positive plant-plant interactions.

Towards evidence for plant-bacteria coevolution: an ecophylogenetic framework reveals selection through niche construction

Bouchenak-khelladi Y¹, Angot V

¹Université Bourgogne Europe

POSTER SESSION 1 - **P01.198**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Biotic interactions are responsible for major evolutionary changes across multiple spatial and temporal scales.. One of the most intricate and complex biotic interaction is the association between plants and microorganisms that may have originated around 460-475 Mya. The extent to which coevolution may drive natural selection and shape angiosperm diversity is still debated, particularly because no unequivocal evidence has been provided regarding reciprocal evolutionary changes. Understanding if plant-driven niche construction led to phylogenetically structured microbial communities is crucial, as it can reveal how plants selectively and consistently shape their associated microbiota through space and time, offering an opportunity for identifying coevolutionary dynamics between plants and their microbiota. The concept of coevolution is still subject to multiple debates and, apart from semantic questions, reflects the need to develop experimental approaches which take into account the complexity of biotic interactions. Despite the known benefits of plant microbiota on growth and nutrition, the mechanisms of association remain largely unknown whereas they do constitute the basis and requirements for coevolution to occur. We used a spatio-temporal experimental approach under controlled conditions where we grew 108 *Pisum* spp.

(Fabaceae; Fabeae) accessions and investigated the composition and structure of bacterial communities in distinct plant-associated microhabitats (rhizosphere, rhizoplane and endosphere) at different growth stages (vegetative, flowering and seed filling). Using full-length 16S rRNA gene sequencing, we inferred a phylogeny for 1604 ASVs present in a bulk soil and analyzed their relative abundances across a spatial (i.e. plant-associated microhabitats) and temporal (i.e. plant growth stages) gradient. We found that temporal and spatial changes in the composition and structure of bacterial communities were coupled with shifts in phylogenetic diversity and followed both over- and underdispersion models along a spatial gradient. Our findings suggest that plants play a role in driving the evolution of bacterial communities through niche construction. We argue that plant-microbiota interactions illustrate pairwise coevolution, where both plants and bacteria act as active niche constructors, shaping their shared environment and adapting to the changes they induce. We will discuss how our ecophylogenetic approach can be used to explore plant-microorganisms' interactions to disentangle the mechanisms (i.e. traits under reciprocal selection) and dynamics (i.e. plant-bacteria phylogenetic correlations) shaping these associations in light of coevolutionary processes.

Transcriptomic signatures of infection and insights into transgenerational immune priming in an invertebrate host

Paraskevopoulou S¹, Gattis S¹, Ben-ami F¹

¹George S. Wise Faculty of Life Sciences, Tel Aviv University

*POSTER SESSION 1 - **P01.204**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Parasites impose substantial fitness costs on their hosts, often triggering complex immune and life-history responses. Recent evidence suggests that invertebrates, despite lacking a sophisticated adaptive immune system like vertebrates, can influence the immune response of their offspring and of subsequent generations, a phenomenon known as immune priming. However, the molecular mechanisms underlying both within- and transgenerational immune response remain largely unexplored, particularly in non-insect invertebrates.

Using the *Daphnia magna*–*Metschnikowia bicuspidata* host-parasite system, we first investigated within-generational transcriptomic and phenotypic responses to infection. Exposed-uninfected individuals upregulated genes associated with haemocyte recruitment and gut epithelium reinforcement, suggesting that enhancing structural barriers may contribute to parasite resistance. These individuals also delayed reproductive maturation, likely reflecting a cost of immune activation, but maintained reproductive output over time. Thus, overall fecundity was compensated later in life. In contrast, infected individuals exhibited metabolic shifts consistent with host

exhaustion, aligning with the terminal investment hypothesis, whereby resources are reallocated from somatic maintenance to immediate reproduction under high mortality risk.

In transgenerational comparisons, both maternal and grandmaternal immune priming resulted in upregulation of genes encoding RNA polymerase subunits, suggesting an enhanced transcriptional activity as a conserved signature of immune priming. However, grandmaternal priming induced a significant downregulation of genes involved in DNA replication, repair, and proteolysis, suggesting a more extensive regulatory shift. The increased number of differentially expressed genes in grandmaternal priming compared to maternal aligns with previous findings in *Daphnia* that transcriptional responses to environmental cues can intensify across generations.

Our findings provide novel insights into the molecular and physiological mechanisms of invertebrate immune responses, shedding light on both within- and transgenerational strategies that shape host responses to parasitic infection.

Twenty-years of Tuberculosis-driven selection on meerkat MHC

POSTER SESSION 1 - P01.224, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Pathogen-mediated balancing selection (PMBS) drives host evolution across the tree of life. Distinguishing between the three main mechanisms underlying PMBS, i.e., rare-allele advantage, fluctuating selection and heterozygote advantage, remains difficult, limiting our understanding of frequency-dependent adaptations by hosts and counter adaptation by pathogens. Here, we leverage immune genetic and disease surveillance data from over 1,500 wild meerkats (*Suricata suricatta*) to track how selection by the tuberculosis (TB)-causing *Mycobacterium suricattae* shaped the evolution of the Major Histocompatibility Complex (MHC) over two decades. Compared with neutral genetic markers, we detect more rapid differentiation and recycling of alleles at the MHC-DRB loci, suggesting that TB imposes

strong PMBS on wild meerkats. In addition, we show that meerkats carrying the MHC allele Susu-DRB*13 were initially more likely to be infected with TB, with the effect reversing over the course of the study, followed by an increase in the frequency of Susu-DRB*13. Meerkats carrying Susu-DRB*13 also showed slower progression to TB symptoms and longer survival once clinical signs of TB appeared. Life-time reproductive success reflected the resistance effect conferred by Susu-DRB*13. Based on several lines of evidence, we propose that the recycling of a rare-allele or fluctuating selection, rather than heterozygote advantage, drive our observation in this longitudinally sampled wild mammal population.

Unraveling the molecular basis of host plant adaptation in a generalist herbivore

Villacis Perez E¹, De Graeve F², De Beer B², Ali Alshami S¹, de Jong R¹, De Meyer T², Van Leeuwen T²

¹University of Amsterdam, ²Ghent University

POSTER SESSION 1 - P01.220, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The antagonistic interactions between plants and herbivores promote evolutionary change. Studying the evolution of herbivore adaptation to different host plant species is a fundamental cornerstone of evolutionary biology with clear applications for sustainable pest management. Generalist herbivores, which can colonise multiple host plant species are of particular interest, as hybridization between genetically distinct populations can increase the standing genetic variation and therefore the adaptive potential of the species. To identify the genetic basis of host plant adaptation we focus on *Tetranychus urticae*, a generalist mite known for its adaptive potential, which is evidenced in its immense host range and ability to develop metabolic resistance to xenobiotics. Despite its widespread distribution and detrimental effect to crops, the molecular underpinnings associated with the potential of host adaptation and the consequences of host adaptation in this, and many other pests remain elusive. Here, we conduct two experimental approaches in

parallel, to identify and map the genetic basis of host plant performance and adaptation in genetically distinct populations of *T. urticae*. We create a genetically diverse mite population in the laboratory, subject it to selection using a challenging plant for spider mites, tomato, and map genomic regions linked to the phenotypic evolution of increased reproductive performance. In parallel, we map genomic regions responsible for performance on tomato segregating in field mite populations, by comparing the genomes of pooled individuals from an F2 backcross between populations with high and low reproductive performance on tomato. Both approaches revealed specific and shared genomic regions associated with host plant performance and adaptation and key candidate genes were identified. Our findings highlight the power of spider mite genetic approaches to identify the complex genetic basis of host adaptation in generalist herbivores.

When Durum Wheat grows together with Alfalfa: The Genetic Dialogue of Neighboring Plants

Salas N¹, Beloglasov M¹, Voiry C¹, Tollon-Cordet C², Bernazeau B², Julier B³, Baranger A², David J¹

¹Institut Agro Montpellier, ²INRAE, ³INRAE

POSTER SESSION 1 - **P01.226**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Growing environmental constraints and the need for more sustainable food systems promote crop diversification and the harnessing of ecological processes to enhance resilience and reduce external inputs. Among the promising strategies, intercropping—growing multiple species together—optimizes resource use and fosters beneficial plant-plant interactions (Cougnon et al., 2022). However, designing productive and stable species mixtures requires both careful management of within-species variability and a better understanding of the genetic mechanisms underlying such interactions.

Plant-plant interactions are major drivers of individual performance and community outcomes. In crop mixtures, they include both intra- and interspecific processes that shape competition, facilitation, and resource allocation. While their ecological consequences have been widely studied (Becker et al., 2023), their genetic basis—and especially their potential to evolve—remains underexplored. We address this gap using a model intercrop composed of *Triticum durum* (wheat), an annual income species expected to enrich grain protein content, and *Medicago sativa* (alfalfa), a perennial service species contributing to weed control and nitrogen input. This cereal-legume combination offers a compelling system to investigate interactions between species with complementary functions and life histories.

To dissect these interactions, we rely on an individual-centered experimental design, where focal wheat plants are surrounded by variable neighbors from both species. This layout captures the intra- and interspecific genetic context in which each individual develops. By manipulating the genetic composition of neighbors, we analyze how their identity and diversity shape the phenotype of focal plants.

We apply a quantitative genetic model estimating direct genetic effects (DGEs)—due to an individual's own genotype—and indirect genetic

effects (IGEs)—due to the genotypes of surrounding individuals (Bijma et al., 2007). Our model extends these concepts across species boundaries, capturing how a wheat genotype affects neighboring wheat and alfalfa plants, and vice versa. This is especially relevant in cereal-legume systems, where traits like nitrogen fixation or canopy architecture drive strong facilitative interactions.

By partitioning phenotypic variance into intra- and interspecific genetic components and estimating covariances among them, we gain insights into how selection may act not only on individual performance but also on the ability to influence or respond to neighbors. Across functional traits (e.g., tiller number, plant height, leaf nitrogen), agronomic traits (e.g., biomass, yield components), and spectral data (NIRS of leaves and grains), we show that phenotypes are shaped by both self-genotype and the genotype of multiple neighbors.

We demonstrate the existence of heritable interactions at both intra- and interspecific levels. For wheat, we estimate pseudo design heritabilities for DGEs and IGEs of 0.57 and 0.29 (plant height), and 0.52 and 0.26 (leaf nitrogen), confirming the capacity of our design to detect both. Simulations suggest these effects can evolve over time, shaping trait trajectories and breeding outcomes.

By formalizing multispecies genetic interactions in an individual-centered framework, our work bridges quantitative genetics, evolutionary biology, and agroecology. It offers a novel lens to study cooperation and competition in crop mixtures and a practical toolbox for their design. This approach opens new perspectives: in breeding, by accounting for neighbor effects in both pure and mixed stands; in evolutionary biology, by exploring how interspecific interactions drive trait coevolution; and in agroecology, by illuminating the mechanisms behind facilitation and complementarity.

Zostera marina and Labyrinthula spp.: Exploring Pathogen Virulence and Host Defense Across A Thermal Gradient

Schuster J¹, Bakowski C¹, Stukenbrock E², Brakel J³, Moro I⁴, Reusch T¹

¹Marine Evolutionary Ecology, GEOMAR Helmholtz Centre For Ocean Research Kiel, ²Environmental Genomics, Christian-Albrechts University Kiel, ³Helmholtz Institute for Functional Marine Biodiversity (HIFMB), University of Oldenburg, ⁴General Botany, University of Padova

POSTER SESSION 1 - P01.218, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Seagrasses are a unique group of marine flowering plants that comprise 72 species forming large meadows in coastal waters around the globe, except Antarctica. By providing various ecosystem services, such as carbon sequestering, coastal protection, and biodiversity enhancement, seagrass meadows are among the most productive ecosystems. Despite their ecological importance, seagrass ecosystems are experiencing widespread and accelerating declines. Losses are driven by a combination of anthropogenic and natural stressors, including eutrophication and direct habitat destruction. Natural threats such as eelgrass wasting disease, caused by the causative agent *Labyrinthula zosterae*, have only recently come into focus. This protist is ubiquitous in seagrass meadows of various species and can induce necrosis and ultimately death in affected plants, while it is often asymptomatic. The most prominent virulent outbreak occurred at the Western Atlantic Coast in the 1930's diminishing the abundance of eelgrass to 10% of the initial population.

Previous studies involving the temperate seagrass species, *Zostera marina*, inoculated with *Labyrinthula* spp. have demonstrated highly dynamic host-pathogen-environment interactions that cannot be readily explained and appear to shift in response to changing environmental conditions. To further investigate these dynamics, we will employ a temperature gradient-based approach (ranging from 20-30°C) to identify a thermal threshold at which the Eelgrass-*Labyrinthula* interaction may shift from a non-pathogenic to a pathogenic relationship, thereby affecting the performance of both host and pathogen. Seeds of Baltic *Zostera marina* were surface-sterilized to reduce the likelihood of pre-existing *Labyrinthula* contamination and subsequently

planted in climate-controlled chambers. Additionally, Mediterranean seedlings were grown from non-surface sterilized seeds. Moreover, two *Labyrinthula* spp. strains were isolated from Baltic and Mediterranean eelgrass plants and cultivated on seawater-agar medium plates. Strains and plants from two different bioregions will be used since localized historical outbreaks may have driven host populations to evolve mechanisms of tolerance to *Labyrinthula* infection. Moreover, not all *Labyrinthula* strains exhibit virulence toward host populations, potentially due to specific host and pathogen genotype interactions, that formed in co-evolution and local adaptation. These processes could be disrupted by changes in biotic and abiotic conditions. Baltic and Mediterranean eelgrass plants will be inoculated in a crossed design with both *Labyrinthula* strains and exposed to a range of 11 different temperatures representing benign to extreme temperature stress over a period of three weeks, including a recovery phase. Inoculation success will be quantified using qPCR to determine the abundance of *Labyrinthula* cells on eelgrass tissues. In addition, host and pathogen performance will be evaluated through gene expression patterns, morphometric parameters including plant survival and growth rates, and stress indicators such as photosynthetic and respiratory rates. To date, we have successfully isolated multiple *Labyrinthula* strains from both the Baltic and Mediterranean Seas and have begun preliminary inoculation trials. Our upcoming results will provide valuable insights into species-specific host-pathogen interactions and how these are modulated by temperature, thereby advancing our knowledge of the mechanisms driving seagrass wasting disease.

Bacteria-phage coevolution drives patchy distribution of plant disease through phage resistance-virulence trade-offs

Friman V^{1,2,3}, Wang X³, Franco Ortega S², Yang K³, Wang S³, Wei Z³

¹University of Helsinki, ²University of York, ³Nanjing Agricultural University

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

Bacteria-phage coevolution is pervasive in nature, affecting the global nutrient cycling and the composition and functioning of microbial communities. While reciprocal adaptations often have correlated fitness effects on coevolving species, it is unclear how these changes cascade in food webs, affecting the ecology of the surrounding communities. Here, we used a combination of field, greenhouse and lab experiments to link coevolutionary patterns between phytopathogenic *Ralstonia pseudosolanacearum* bacterium and its phage parasites to bacterial wilt plant disease patterns in tomato fields. By sampling four geographically disconnected fields, we show that bacteria and phages are locally adapted between and within fields, where phages had the highest infectivity on

sympatric bacteria and bacteria showed the highest resistance when isolated from the healthy versus diseased plants. The modularity of phage-bacteria coevolution could be explained by field-specific anti-phage defense system patterns and direct experiments where phages selected for field-specific mutations in different phage receptor genes. Crucially, phage resistance showed strong antagonistic pleiotropy with virulence measured in planta, explaining why phage-resistant but weakly virulent pathogen isolates were associated with healthy tomato plants within fields. Our findings demonstrate that bacteria-phage coevolution can cascade through trophic networks, driving a patchy plant disease distribution through phage resistance-virulence trade-offs.

Changing the script: ecological reversal of predator–prey roles in microbial communities

Vasse M^{1,2}, Fiegna F², Kriesel B², Velicer G²

¹CNRS, ²ETH

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Ecological variation influences the character of many biotic interactions, but examples of predator–prey reversal mediated by abiotic context remain rare. We show that the temperature at which prey are grown before interacting with a bacterial predator can determine the very direction of predation, reversing predator and prey identities. While *Pseudomonas fluorescens* reared at 32°C was extensively killed by the generalist predator *Myxococcus xanthus*, *P. fluorescens* reared at 22°C became the predator, slaughtering *M. xanthus* to extinction and growing on its remains. This reversal was not limited to a single species pair: diffusible molecules produced by *P. fluorescens* also killed two other

phylogenetically distant bacterial species, among several examined.

Our results suggest that predator and prey identities may not be intrinsic properties of species, but rather context-dependent roles that can shift with environmental conditions. They also suggest that a larger proportion of microbial warfare results in predation—the killing and consumption of organisms—than is generally recognized.

More broadly, our findings support the view that biotic interactions move along dynamic continuums rather than occupy rigid categories, and highlight how integrating ecological variability into evolutionary frameworks could open exciting ways to look at natural communities and their responses to rapid environmental change.

Co-circulation and co-infection: parasite evolutionary ecology across scales

Zilio G¹, Dean A², Bayona J¹, Duncan A¹, Ezenwa V³, Fenton A², Gjini E⁴, Magalhães S⁵, Michalakakis Y⁶, Mideo N⁷, Pedersen A⁸, Taguchi L⁷, Tollenaere C⁹, Zélé F¹, Kaltz O¹

¹ISEM, University of Montpellier, CNRS, ²University of Liverpool, ³Yale University, ⁴Instituto Superior Técnico, University of Lisbon, ⁵Faculdade de Ciências, Universidade de Lisboa, ⁶MIVEGEC, University of Montpellier, CNRS, ⁷University of Toronto, ⁸University of Edinburgh, ⁹PHIM, University of Montpellier, IRD

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Multiple parasites strain and/or species often co-circulate simultaneously in the same host population or even co-infect the same host individuals. Each process – co-infection and co-circulation, respectively – can lead to interactions between parasites. For example, parasite can interfere with each other directly within the same host individual, or indirectly by removing susceptible hosts from the population. However, co-infection and co-circulation are often investigated by different fields (e.g., immunology versus epidemiology). This has resulted in a fundamental gap in our understanding of how parasite interactions at these two levels affect each other, and on the long-term evolutionary implications.

I will present a framework aimed at bridging between individual- and population-level perspectives of interactions among parasites, developed by a consortium of evolutionary biologists and ecologists investigating the topic from theoretical, experimental and field perspectives. First, we employed the Susceptible-Infected framework to characterise the potential range of individual- and population-level host interactions that may occur among co-circulating parasites. Second, we mapped

empirical examples from the literature onto this framework, to illustrate the mechanisms driving both types of interactions across diverse host-parasite systems and the evolutionary consequences. I will also briefly present results from an ongoing project, combining experimental investigations of co-infection and co-circulation dynamics in an aquatic model system with mathematical modelling.

Careful modelling and experiments can help disentangling when interactions at one scale affect those at another, and how ascribing a pattern to a within-host mechanism that is in fact driven by a between-host process (or vice versa) can be misleading. Given the steady rise of emerging and re-emerging infectious diseases, novel parasite combinations are increasingly likely to be brought together, resulting in new and more frequent interactions and opportunities for selection and evolutionary changes to occur. Thus, better understanding of general rules for interactions between parasites, and key sources of variation in outcomes, will provide insight for public health, conservation and agriculture, all of which is all the more important in the current context of rapid global change.

Coinfection with a both a competitor and a facilitator parasite increases within-host growth rate and transmission

Duncan A¹, Grosjean S¹, Bernard C¹, Wehrung M¹, Person G¹, Gupta V¹

¹Institute of Evolutionary Sciences, Montpellier CNRS

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Parasite-parasite interactions are predicted to impact parasite life-history evolution, including virulence and transmission. For instance, competition among parasites for shared host resources or mediated via the immune system can select for higher virulence and transmission. There may also be positive interactions among parasites, but less is known about how facilitation might impact parasite evolution.

This experiment investigates how evolution of the spider mite *Tetranychus evansi* in coinfection with a competitor, another spider mite *T. urticae*, or a facilitator, Tomato spotted wilt virus (TSWV), impacts life-history evolution on tomato plants. *T. evansi* competes with *T. urticae* for shared host resources and via the plant immune system, whereas TSWV has a positive effect on *T. evansi* life-history traits, possibly via negative immune cross talk. We used experimental evolution to evolve *T. evansi* on tomato plants in 1. coinfection with *T. urticae*, 2. coinfection with TSWV, or 3. in single infections over > 18 generations.

Following, 18 generations we assessed how *T. evansi* life-history traits (including virulence and transmission) evolved in the different coinfection treatments on leaf discs and whole plants. We are currently extracting virulence traits.

On leaf discs, *T. evansi* evolved in coinfection with either TSWV or *T. urticae* produced a

higher number of adult daughters and had earlier transmission than *T. evansi* that evolved in single infection at low densities. Similarly, on whole plants preliminary results suggest that transmission is higher for *T. evansi* lines that evolved in coinfection with TSWV or *T. urticae*.

Thus, as predicted, evolving in coinfections with a competitor increases within-host growth and transmission. It is not immediately clear why evolution under facilitation with TSWV had the same effect, but it is possible that TSWV increases intraspecific competition, both directly due to higher growth rates and indirectly by reducing host plant size and thus available resources.

When in coinfection with *T. urticae*, or at higher *T. evansi* densities, there was no difference due to evolution regime (single or coinfection) in offspring production or transmission, showing that evolving with a competitor parasite did not increase competitive ability. In contrast, *T. evansi* evolved in coinfection with TSWV had a weaker effect on *T. urticae*, enabling them to produce more offspring that became adult. The reason for this is not entirely clear, but this result does show that evolving in coinfection with one parasite (TSWV) can change the outcomes of coinfection for another parasite (*T. urticae*).

Competition and facilitation at the within- and between-host levels between spider mites evolving in metal-accumulating plants

Fragata I, Godinho D, R Rodrigues L, Cruz M, Godoy O, Magalhães S

¹Ce3c Centre For Ecology Evolution And Environmental Changes, Faculdade De Ciências, Universidade De Lisboa, ²Gulbenkian Institute for Molecular Medicine GIMM, ³Estación Biológica de Doñana (EBD-CSIC)

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

Evolution can alter coinfection dynamics by modifying traits involved in transmission between hosts, a possibility that has been poorly studied, especially in a heterogeneous host population. Here, we test how evolution of ectoparasitic spider mites on tomato host plants affects their transmission in different scenarios. To do so, we performed experimental evolution of *Tetranychus urticae* or *T. evansi* on tomato plants that accumulated cadmium or not. Then, we measured how evolution affected transmission and host choice in presence or absence of competitors and population growth rates in competition in a heterogeneous environment. We did not detect signs of adaptation to that heterogeneous environment in the *T. urticae*

populations. However, *T. evansi* populations evolving in cadmium had higher growth rates in that environment than control populations. Moreover, when placed together on leaves with cadmium, both species dispersed more than from leaves with no cadmium, but only when the competitor evolved in cadmium. Similarly, when together, both species increased their preference toward leaves with cadmium, but only when *T. evansi* evolved in cadmium. This suggests that evolution within a host modifies traits that are expressed between different types of hosts. Hence, evolution can shape coinfection dynamics of two species by modifying traits that affect transmission dynamics between hosts.

Costs of immunity avoided by immune suppression in novel terminal investment response

Priest N¹, Liu J¹

¹University of Bath, Milner Centre for Evolution

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Immunity is not only costly for the host but can drive an arms race stimulating the evolution of lethal microbes. However, eco-immunity research has not established whether animals have evolved different mechanisms to manage common infections or determined whether host responses could, in fact, drive the evolution of mutualisms. Here, we show that insects do not fight common low-dose topical infections with immunological mechanisms that improve post-infection survival; instead, they employ terminal investment mechanisms that enhance reproduction with immediate survival costs. We focus on when, how, and why insects adopt terminal investment and how these responses contribute to the evolution of mutualisms. We demonstrate that the fruit fly, *Drosophila melanogaster*, responds to low-dose topical exposures of endemic fungi by succumbing to infection via low-cost terminal

investment, while combating high-dose infections with reproductively detrimental immune responses. Our discovery of a low-cost reproductive strategy mediated by Turandot C (TotC) represents the first non-immunological genetic mechanism. The contrasting fitness effects of the expression of TotC and the canonical immune gene Df show that terminal investment operates through stress-responsive pathways divergent from innate immunity. And, we show how recent mathematical modelling illuminates how life history responses can contribute to the evolution of host-microbe mutualisms. Our study is important because it shows how evolution of immune suppression in the host can be cost-effective for the host. It identifies key fitness trade-offs that limit the evolution of defence against infection. It suggests that variation in how hosts respond to infection contributes to the antagonism / mutualism continuum.

Evolution of buzz pollinated flowers in response to pollen-feeding insects: Pollen dosing in response to vibrations

Vallejo Marin M¹, Lundgren A¹

¹Uppsala University

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Although many plant species use nectar and other resources to attract and reward floral visitors, thousands of nectarless species rely on pollen as the main reward. By consuming pollen, which in this case function as both the carriers of the plant's male gametes and food for visitors, floral visitors can impose conflicting selective pressures on pollen removal. Previous work has shown that successful pollen export to other plants is a decelerating function of the amount removed per visit. Thus, removing more pollen per visit does not necessarily translate to more pollen exported. Plants have therefore evolved strategies that allow them to control the amount of pollen removed per visit, i.e., "pollen dispensing" strategies. About 20,000 species of flowering plants have evolved specialised flowers that conceal pollen inside tubular structures, usually anthers, that open only through small pores at the tip. These tube-like or poricidal anthers potentially control pollen dispensing. Yet, some bee species have evolved the capacity to produce high-power

vibrations that shake pollen out of poricidal anthers and could overcome this dispensing mechanism. Here we present the results of experimental studies assessing pollen release during floral visits involving vibrations (buzz pollination). Specifically, we assess how the type of pollination vibrations affects the amount and rate of pollen released. To do this we use a combination of experiments with bumblebees and with mechanical shakers where we can mimic vibrations produced by different types of bees on flowers of the genus *Solanum*. Our results suggest that poricidal flowers strongly limit pollen release during single visits suggesting that they work as pollen dispensing mechanisms. Our findings suggest that in addition to the physical constrain of pollen release by the evolution of small anther openings, other developmental processes are involved in limiting the amount of pollen that bees can removed from buzz pollinated flowers during individual visits.

Evolution of the plasticity of pathogen virulence in temporally and spatially variable environments

Kumata R¹, Lion S¹, Westra E², Gandon S¹

¹CNRS CEFE, ²Environment and Sustainability Institute, Biosciences, University of Exeter,

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Some pathogens have evolved the ability to plastically adjust their infection strategies to cope with the variability of their environment. Yet the ecological conditions promoting the evolution of pathogen plasticity remain unclear. Here we analyse the evolution of a pathogen with the ability to perceive the infection status of neighbouring hosts and we explore when this information may favour the evolution of plastic virulence strategies. First, we show that virulence plasticity does not evolve when the environment is constant. Second, we show that temporal or spatial fluctuations of the environment can promote the evolution of lower virulence in informed pathogens because the signal

perceived by the pathogen provides an indirect information on the change of the quality of the environment. This indirect information takes the form of a negative covariance between the perception of the signal and the availability of susceptible hosts. We explore and contrast the influence of temporal and spatial structure on the evolution of plasticity. This work clarifies the conditions promoting the evolution of phage communication systems such as Arbitrium. More generally, this analysis provides a general theoretical framework to understand the adaptive nature of communication and plastic life-history strategies of microbes in variable environments.

From mosquitoes to cuckoo bumblebees; selfish genetic elements to spotted hyenas; penguins to pathogens: can we explain how antagonists choose their victim?

Attwood M¹

¹Dept. of Zoology, University Of Cambridge

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

The way in which antagonists choose their victim is fundamental to antagonistic interactions. In this talk, I will argue that a trade-off between victim quality and vulnerability generalises across interactions – from klepto-parasites, selfish genetic elements, host-consuming parasites and brood parasites, to pathogens, predators and herbivores.

This framework defines quality as the value of resources a host has, and vulnerability as the ease with which a parasite can obtain those resources. Parasite ‘choice’ can refer to flexible decision-making or to specialisation over evolutionary time. A parasite can choose a low-quality host, which is easier to attack but offers limited resources; or a high-quality host, which is more challenging to attack but offers more resources if the parasite is successful. For example, louse flies can take larger blood meals from chicks in good body condition, but face weaker immune defences from chicks in poor body condition (Bize et al., 2008). Similarly, klepto-parasitic gulls obtain higher-value food items from adult pelicans, but can more easily steal food from juvenile pelicans (Carroll & Cramer 1985).

The optimal decision for a parasite will depend on its ecology and the shape of the trade-off in a given system. I will first discuss the conditions required for the trade-off to apply. Many studies of different types of parasitism and predation across taxa have

investigated traits pertaining to quality or vulnerability, but their findings have not previously been integrated. Doing so makes it possible to draw out broad principles that determine whether quality or vulnerability has the greater impact on host choice. For example, vulnerability becomes more important when parasites manipulate host quality post-infection (e.g. via parasitic castration).

This approach can help resolve contradictory findings, such as why the same parasites choose high-quality hosts in some studies, and low-quality hosts in others. It can be used to project the effects of global change on host-parasite and predator-prey dynamics. Factors which directly affect host quality, such as food availability and the presence of toxins, are currently experiencing dramatic shifts due to climate and other sources of anthropogenic change. This predicts shifts in the optimal victim based on the trade-off between quality and vulnerability.

The framework also creates an integrated perspective on coevolutionary adaptations. Across systems, hosts evolve lower vulnerability – or, rarely, lower quality (e.g. bacteria depleting their own deoxynucleotides in response to phage infection). Hosts can manipulate parasite choice by deceptively signalling low quality (e.g. thanatosis, masquerade) and low vulnerability (e.g. Batesian mimicry).

I'm the captain now: Host fitness is predicted by host life-history strategy in an emerging model host-parasite system

Fouilloux C¹, Compton J¹, Srinivas I¹, Schuldes M¹, Rollo A¹, Paulman R¹, Hite J¹

¹University Of Wisconsin

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Parasitic manipulation of hosts can alter resource allocation, impacting both individual fitness and population dynamics. Zooplankton, the first animal link in many aquatic food webs, are hosts to thousands of parasites distributed globally, yet the consequences of their infections remain understudied. This gap is especially critical given their role as first intermediate hosts for parasites involved in Neglected Tropical Diseases (NTDs), where unresolved early-stage dynamics complicate disease control. In trophically transmitted parasites, where hosts do not recover from infection, life-history theory predicts increased reproductive effort following exposure and reduced fecundity after infection due to resource depletion. Using an emerging model system of the cyclopoid copepod *Acanthocyclops robustus* and the trophically-transmitted tapeworm *Schistocephalus solidus*, we tested these predictions in controlled laboratory settings. We find that exposed (but uninfected) females amplify their reproductive effort: they produce larger and more frequent

clutches, consistent with adaptive reallocation toward reproduction under infection threat. In contrast, infected females become sterile, ceasing reproduction despite prior mating and known sperm storage capacity. Parallel experiments testing resource scarce conditions suggest that sterility is not explained by energetic limitation alone, positioning *S. solidus* the culprit for the fecundity loss in copepod hosts. These results offer empirical support for theoretical models predicting strategic reproductive shifts in hosts prior to infection and sterility post-infection in response to resource-depleting parasites. By disrupting copepod fecundity, a high prevalence of infected individuals may alter zooplankton population dynamics. Shifts in primary consumer population structure have implications for both ecosystem stability and the availability of suitable hosts for parasites, both of which are critical for ecological forecasting and the control of NTDs.

Landscape structure as a driver of eco-evolution in host-parasite systems

Deshpande J, Dakos V, Kaltz O, **Fronhofer E**¹

¹Isem – Cnrs

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

Spatial network structure of biological systems drives ecology and evolution by distributing organisms and their genes. The ubiquitous host-parasite systems are no exception. However, past theoretical work has largely focused on simple spatial structures, such as grids, hampering the translation of theoretical predictions to real ecosystems. Thus, we develop an eco-evolutionary metapopulation model of host-parasite dynamics where hosts and parasites disperse through realistically complex spatial networks representing major biomes using river-like and terrestrial-like networks. We generate the testable

prediction that parasite virulence, or how parasites harm their hosts, peaks at intermediate dispersal values in river-like systems while it increases with increasing dispersal in terrestrial-like systems. In river-like systems, virulence also reaches higher overall values. Moreover, we explore the evolution of further interaction traits, such as dispersal and resistance in a 3-dimensional trait space. Our study highlights how eco-evolutionary feedbacks can be understood in light of spatial network structure by linking network topology to classical evolutionary mechanisms such as kin selection.

Macroevolutionary Patterns in Trees Shaped by Three Key Mutualisms: Pollination, Seed Dispersal, and Mycorrhizal Symbiosis

Yamawo A¹, Ohno M

¹Kyoto University

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

Mutualistic interactions such as mycorrhizal symbiosis, seed dispersal, and pollination are key drivers of plant diversification in terrestrial ecosystems. Yet, we still lack a clear understanding of how these interactions have evolved together to shape global patterns of tree diversity. In this study, we analyzed the joint evolutionary patterns of mycorrhizal type, seed dispersal mode, and pollination mode using two global databases: one with 699 tree species based on direct field observations of mycorrhizae, and another with over 10,000 species based on phylogenetic inference. Despite differences in data certainty and coverage, both datasets showed consistent results.

We found strong evidence of co-evolution among the three traits. Arbuscular mycorrhizal (AM) trees are typically associated with biotic seed dispersal and pollination, which promote long-distance gene flow. In contrast, ectomycorrhizal (EM) trees are more likely to have wind-driven seed and pollen dispersal, linked to shorter-range processes. Our findings suggest that mutualistic syndromes involving belowground and aboveground partners have evolved in concert and have played a central role in the macroevolutionary diversification of trees across ecosystems worldwide.

Repeated breakdowns of mutualism into parasitism and expansions of ecological opportunity in a globally distributed plant-insect symbiosis

Hembry D^{1,2}, Luo S³, Liu T³, Wang Z³, Wu Y³, Duarte J^{2,4}, Fowler J⁵, Whiteman N⁶, Dlugosch K²

¹James Madison University, ²University of Arizona, ³South China Botanical Garden, ⁴Pima Community College, ⁵University of Miami, ⁶University of California, Berkeley

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Background: Although mutualism is commonly thought to be inherently unstable because of the opportunity for selection to favor antagonism by interacting partners, few macroevolutionary transitions from mutualism to parasitism have been reported. Leafroller moths (Lepidoptera: Gracillariidae: Epicephala) are distributed throughout tropical and warm temperate regions of the Old World, where most are specialized pollinating seed predators (in a manner analogous to fig wasps or yucca moths) of their host leafroller plants (Phyllanthaceae: Phyllanthaeae). Mutualistic leafroller moths actively pollinate their hosts' flowers, but oviposit into the flowers' ovaries, where the larvae consume a subset of the hosts' seeds. This interaction is characterized by high biological intimacy, and thus has many parallels to fully symbiotic mutualisms. Multiple losses of pollination behavior—and therefore of mutualism—have been reported in the literature in leafroller moths in Asia.

Materials and Methods: Here we report the discovery of non-pollinating leafroller moths associated with native species of leafroller plants (*Nellica* spp., *Phyllanthus* spp., *Moeroris* spp.) in the southern United States (Oklahoma, Texas, Louisiana, and Florida). This is the first record of this high-intimacy plant-insect interaction from the Nearctic. Through phylogenetic inference of novel and previously published sequence data from this system globally, we infer the number of transitions to parasitism. We then

use these repeated transitions and phylogenetic comparative methods to ask questions about the changes associated with mutualism breakdown in the biology of leafroller moths.

Results: Phylogenetic analysis of data from the literature combined with novel sequence data from Asia and North America reveals that this mutualism has broken down into parasitism at least seven times, and possibly more frequently. This mutualism has thus evolved into parasitism more frequently than any other mutualism known to date. We find that in some of these lineages, loss of mutualism is associated with transitions among distantly related host plants and colonization of new continents.

Conclusions: These results indicate that some mutualisms are highly prone to breakdown, and that a macroevolutionary perspective on the fates of these parasitic lineages may reveal how mutualisms persist through evolutionary time. These results specifically suggest that mutualism breakdown may in some cases offer substantial expansion of ecological opportunity. However, as far as is known, mutualism loss only occurs from the insect side of the interaction; no losses of moth pollination are yet demonstrated in Phyllanthaeae. I then discuss the implications of these findings for studies of mutualism loss in other symbioses.

Reversal of host-parasite dynamics following an introduction of non-native species

Reichard M¹, Douda K², Vrtílek M¹, Smith C¹

¹Czech Academy Of Sciences, ²Czech University of Life Sciences

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

Intimate interspecific relationships often exhibit coevolutionary dynamics, shaped by reciprocal adaptations and counter-adaptations. These interactions can shift along a continuum from mutualism to commensalism or parasitism. Biological invasions, by introducing novel partners in such relationships, provide valuable natural experiments to test predictions from ecological and evolutionary theory. We investigated how the invasion of the Chinese pond mussel (*Sinanodonta woodiana*), native to East Asia, affects the unique reciprocal relationship between the European bitterling (*Rhodeus amarus*) and native European unionid mussels. In this association, bitterling fish deposit their eggs in the gills of live mussels, while mussel larvae (glochidia) parasitize on fish fins and gills. In Europe, *R. amarus* is a parasite of mussels: it exploits all native mussel species for oviposition, while effectively resisting infestation by their glochidia. In contrast, *S.*

woodiana, which co-evolved with a diverse community of Asian bitterling species, exhibits strong defenses against such parasitism. Our experiments revealed that European *R. amarus* is unable to successfully use invasive *S. woodiana* as a host, as Asian *S. woodiana* consistently rejects the eggs of *R. amarus*. Conversely, *S. woodiana* glochidia successfully parasitize *R. amarus*, effectively reversing the traditional host-parasite roles observed in this system in Europe. These findings highlight how novel ecological associations produced by biological invasions can restructure established interspecific relationships and suggest potential consequences for the population dynamics of *R. amarus*. We then also experimentally explored and discuss implications of potential invasions by East Asian bitterling species on the nature of relationships and for the population dynamics of the European bitterling fish.

The Legacy of Past Heatwaves on 'Off-Host' Parasite Stages: Reduced Infection Risk and Costs in the Daphnia-Pasteuria system

Boutry J¹, Lavi Shasha N¹, Ben-ami F¹

¹Tel Aviv University

MEETING ROOM 113, August 18, 2025, 10:30 AM - 12:30 PM

Heatwaves challenge our understanding of how environmental stressors reshape host-parasite interactions, particularly during the critical "off-host" stages of endoparasites. These stages, often dismissed as inert and unaffected by changes in their environment, remain a blackbox in ecological research despite their key role in the life cycle of parasites. Here, we examined how heatwaves affect the infectivity and progression of infection of *Pasteuria ramosa*, a bacterial parasite of the planktonic crustacean *Daphnia magna*. In order to measure the respective influences of the bacterial genotype and the heatwaves, we exposed the off-host transmission stages (=spores) from four genetically distinct parasite isolates to three temperature regimes (20°C, 30°C, 40°C), and tested their subsequent effects on host and parasite traits. Heatwaves significantly reduced parasite infectivity, regardless of parasite genotype. Hosts infected with parasite

whose endured a heatwave, harbored abnormal early parasites stages (e.g., less cauliflowers and more grape formations), while late-stages of the parasite remained unaffected across all treatments, thereby ensuring stable reproductive output. Intriguingly, heat-stressed spores induced genotype-specific shifts in their host: one host clone increased castration rates at higher temperatures, while others experienced moderate to dramatic declines. Furthermore, individuals exposed to heat-stressed spores that remained uninfected, exhibited enhanced survival, suggesting reduced costs of resistance against damaged parasites. This study provides insights into how heatwaves, endured only by the parasite, can modulate various aspects of host-parasite interactions, underlying the importance of considering the parasite's environmental history in evolutionary ecology and epidemiology.

Tracing coevolutionary divergence in a host-parasite model system

Lievens E¹, Somtürk M¹, Zemp N², Künzel S³, Feulner P⁴, Becks L¹

¹University Of Konstanz, ²ETH Zurich, ³Max Planck Institute for Evolutionary Biology, ⁴Eawag

MEETING ROOM 113, August 18, 2025, 2:00 PM - 5:00 PM

A major driver of change in biotic interactions is the potential for coevolution between the interacting partners. Experimental coevolution studies have shown that coevolving populations often diverge from one another at the genetic scale, which might have knock-on effects on their future evolution. Identifying the cause of coevolutionary divergence is not trivial: is it caused by one partner, which then drives divergence in the other partner, or by both partners? We investigated this question in a host-parasite model system, the unicellular alga *Chlorella variabilis* and its lytic virus PBCV-1. Experimental coevolution in this system produces repeatable arms races at the phenotype scale (algal resistance and viral host range), but not at the genotype scale (algal and viral mutations). As viral characteristics typically promote parallel evolution, we hypothesized that the divergence of algae and viruses is driven by

an initial divergence in algal resistance functions. To test this, we separated and replicated the first steps of coevolution. We first evolved 22 strains of resistant algae, and showed that they belonged to at least three resistance types. Second, each resistant alga was used to produce a set of ~5 resistance-breaking virus isolates, which were sequenced and tested for parallel mutations. Surprisingly, viral mutations were not parallel: resistance-breaking viruses belonging to the same set could have mutations in genes affecting distinct virion structures (external glycans, hair-like fibers, binding site). Thus divergence in alga-virus coevolution could be caused by both partners. Future work will test the impact of this genetic and functional variation on the long-term evolution of the alga-virus interaction.

S19 - Evolution of symbioses and interactions in microbial eukaryotes

A genomic approach to investigate the specificity of symbiont-conferred defence in the tripartite system aphid – *Hamiltonella* - parasitoid wasp

Moggioli G¹, Vorburger C¹

¹Eawag

POSTER SESSION 2 - **P02.113**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Parasitoid wasps exploit many insect species as hosts by injecting their eggs inside them, allowing the developing larvae to feed on and ultimately kill their hosts. Aphids, however, have evolved a unique strategy to counter parasitoid infections through a facultative symbiosis with the bacteria *Hamiltonella defensa*. The resistance against parasitoid wasps, provided by *Hamiltonella*, is hypothesized to be mediated by toxins, which arrest the development of wasp larvae and are encoded in the bacteriophage APSE associated with this endosymbiont. In *Aphis fabae*, *Hamiltonella*-conferred resistance to parasitoid wasps is highly specific: different combinations of *Hamiltonella* strains and parasitoid wasp genotypes result in higher or lower levels of protection to the aphid. Despite previous efforts, the genomic basis of *Hamiltonella*-mediated toxicity and its specificity in interactions with different parasitoids is not fully understood. To

unravel the genetic mechanisms involved in this tripartite system, we generated 14 high-quality genome assemblies of *Hamiltonella* strains isolated from diverse aphid populations and introduced them into a single clonal genotype of *A. fabae*. Phenotypic data and comparative genomic analyses of *Hamiltonella* and APSE aim to identify key genes and pathways involved in toxicity and in the resulting spectrum of protective phenotypes. Additionally, we examine the co-evolutionary dynamics between *Hamiltonella* and parasitoid wasps, investigating whether specific genomic features of *Hamiltonella* and APSE correlate with resistance to different parasitoid genotypes. This work sheds light on how genetic variation in *Hamiltonella* influences its defensive capabilities, advancing our understanding of the ecological and evolutionary pressures driving this intricate host-symbiont-parasitoid system.

Eco-Evo of Symbiosis: Environmental Heterogeneity Meets Density-Dependent Feedback

Patel M¹

¹University Of Hull

POSTER SESSION 2 - P02.117, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Environmental heterogeneity, host movement, and density-dependent feedbacks are fundamental drivers of host-symbiont interactions, yet existing models rarely integrate all three concurrently. I introduce a spatially structured, two-habitat model that explicitly tracks uninfected hosts, hosts infected by either of two symbiont strains, and the corresponding pools of free-living symbionts in each habitat. This framework incorporates logistic growth for both hosts and symbionts, bidirectional migration between habitats, vertical transmission during host reproduction, and horizontal transmission via environmental exposure to the free-living pool.

In each habitat, hosts reproduce subject to a local carrying capacity that limits birth rates as population density approaches its maximum. A specified fraction of offspring inherit the symbiont from infected parents, ensuring vertical transmission, while the remainder join the pool of uninfected hosts. Uninfected hosts may acquire infection by encountering free-living symbionts shed continuously by infected individuals; these environmental transmission events follow a mass-action process. Infected hosts experience strain-specific mortality or fecundity adjustments, capturing potential costs or benefits of infection. Host mortality applies to all classes, providing turnover.

The symbiont component of the model consists of two free-living pools, one for each strain, in each habitat. Symbionts grow in the environment through logistic processes limited by a habitat-specific symbiont carrying capacity and decline due to natural decay. Infected hosts shed symbionts at a constant rate into the free pools, coupling host and environmental dynamics. Both hosts and symbionts migrate bidirectionally between the two habitats at defined rates, enabling spatial coupling, potential source-sink dynamics, and the study of spatial spread and persistence.

By coupling the four population classes across the two habitats through ordinary differential equations, the model yields a system that can be analyzed to derive invasion thresholds. And perform adaptive dynamics analysis to find evolutionary stable strategies for symbiont-host coevolution and symbiont transmission modes. .

These modeling and simulation components provide a flexible example for investigating how environmental heterogeneity and density-dependent processes shape the evolution of symbiotic interactions. I will present the model framework, analytical derivations of invasion metrics, and detailed plans for simulation experiments, highlighting opportunities for empirical validation and broader applications.

Few Targets but Broad Effects: Molecular Mechanisms of Host Phenotype Modulation by a Cestode Parasite

Sisternans T¹, Dirksen P², Kaltenpoth M², Libbrecht R³, Foitzik S¹

¹Johannes Gutenberg Universität, ²Max Planck Institute for Chemical Ecology, ³University of Tours

POSTER SESSION 2 - P02.116, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The ability of parasites to modify their hosts' phenotypes has fascinated evolutionary biologists for a long time. Nevertheless, the processes – particularly the molecular mechanisms – that underpin these parasite-induced alterations remain frequently unresolved. The intricate nature of the interactions between endoparasites and their hosts raises the question of how they have evolved. Four different explanations for parasite-induced phenotypic changes in hosts have been put forward, these are: active manipulation, side-effects of manipulation, the involvement of third parties and the defence strategies of the host itself. A comprehensive understanding of these mechanisms is essential for elucidating how complex host phenotype changes are driven and maintained. We therefore set out to investigate these mechanisms in a system where the parasite (the cestode *Anomotaenia brevis*) has multiple profound phenotypic effects on its host (the ant *Temnothorax nylanderi*). Parasitic infection during the larval stage causes reduced melanisation and sclerotization of the ants' cuticle, increases its adult lifespan considerably, causes decreased activity and muscle dystrophia. These phenotypic changes go hand in hand with a large number of transcriptomic changes in the host. We thus set out to investigate the evolutionary strategies and molecular mechanisms underlying these alterations.

To investigate the mechanisms by which the parasite alters host phenotype, we conducted a series of experiments. We examined the parasite's impact on the host gut microbiome using amplicon sequencing, assessed the specificity of the host immune response through a full-factorial design combining cestode infection and a sham bacterial immune

challenge, and analyzed the resulting transcriptomic changes. Moreover, we developed a novel bioinformatic pipeline to link parasite gene expression to host gene expression, enabling the identification of cestode genes that influence specific host pathways.

We detected shifts in the gut microbiome of infected host workers, which showed reduced alpha bacterial diversity and were more frequently dominated by *Entomoplasma*. Whether these microbiome changes are directly caused by the parasite or indirectly by the observed increased longevity and care of infected workers remains unclear. However, they may contribute to behavioural modifications via the gut–brain axis. We also found evidence of immune suppression in infected hosts, with several immune pathways showing opposing expression patterns in response to cestode infection and bacterial challenge. Despite this suppression, antibacterial pathways remained inducible, indicating that the cestode allows the host to defend against microparasites. Integration of host and parasite transcriptomes using weighted gene co-expression network analysis revealed mechanisms of parasite-induced host modulation. Specifically, we identified statistical associations between parasite genes encoding secreted proteins and host gene expression, suggesting that the parasite targets oxidative stress responses, muscle activity, and the melanisation pathway—an important antiparasitic defence in insects.

Our findings indicate that complex phenotypic changes of hosts can be highly interconnected suggesting that parasites can induce extensive and coordinated changes of the host phenotype by targeting a limited set of molecular pathways.

Genetic variation among progeny shapes symbiosis in a basidiomycete with poplar

⁴Laboratory of Evolutionary Genetics, Institute of Biology, University of Neuchâtel

POSTER SESSION 2 - P02.114, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Forest trees rely on ectomycorrhizal (ECM) fungi for acquiring scarce resources such as water and nutrients. However, the molecular mechanisms governing ECM traits remain inadequately understood, particularly the role of intraspecific fungal variation in root-tip colonisation and trophic interactions. This study examined six ECM traits using *Pisolithus microcarpus*, an ECM fungus capable of forming ECM rootlets in poplar. A collection of 40 sibling monokaryons and their parental dikaryon was analysed through genome and transcriptome sequencing to examine quantitative trait loci, gene expression, and mating-type loci. These findings revealed a pronounced phenotypic continuum in poplar root colonisation by sibling monokaryons, ranging from incompatible to fully compatible strains.

Genetic recombination among monokaryons was demonstrated, and genomic regions potentially involved in ECM-fungal traits were identified. Transcriptomic analysis revealed greater differentiation of transcriptomic profiles between fungal strains than between fungal tissues, and uncovered tissue-specific functional responses for ECM and free-living mycelia. Poplar exhibited distinct transcriptomic responses when interacting with different sibling monokaryons and the parental dikaryon. Allele sorting at 11 mating-type loci confirmed the species' heterothallic tetrapolar system. This study advances understanding of the genetic and transcriptomic mechanisms underlying ECM symbioses, highlighting intraspecific fungal diversity's role in forest ecosystem functioning.

Genomic signatures and evolutionary consequences of symbiosis in a beetle-associated fungus

Pitsillides F¹, Berasategui A², Salem H¹

¹Max Planck Institute for Biology, ²Amsterdam Institute for Life and Environment

POSTER SESSION 2 - P02.111, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Insect-microbe symbioses enhance survival, expand ecological niches, and drive evolutionary change by enabling organisms to adapt to diverse environments. However, these relationships are inherently context-dependent, as exemplified by the association between the tortoise beetle *Chelymorpha alternans* (Coleoptera: Cassidinae) and the fungus *Fusarium oxysporum*. In this system, the fungus acts as a defensive ectosymbiont, protecting beetle pupae from predators. In return, the beetle propagates the fungus onto their shared host plant, *Ipomoea batatas*, where *F. oxysporum* switches to a phytopathogenic lifestyle. While the symbiosis is morphologically and functionally conserved across multiple tortoise beetle species, its origin and molecular evolution remained unclear. By integrating short- and long-read sequencing with phylogenetic inference, comparative genomics, and macrosynteny analysis, this study aims to reveal how these associations shape the genomic landscape

of *Fusarium*. Phylogenetic reconstruction of nine *Fusarium* symbionts from different beetle species demonstrate multiple independent acquisitions of the fungal symbiont by the host. The analysis supports an early, ancestral acquisition of the fungal symbionts across early-diverging tortoise beetles, followed by multiple independent replacement events in more derived lineages. Comparative genomic analyses further reveal drastically reduced genomes across these symbiotic species, including some of the smallest genomes assembled to date for a member of the *F. oxysporum* species complex. Lastly, macrosynteny analysis will guide our efforts to uncover large-scale genomic rearrangements and structural variations that are concomitant with a symbiotic transition. Together, these findings will offer key insights into the genomic evolution of *Fusarium*, which retains plant pathogenic potential in light of its association with the beetle.

Genomic signatures of adaptation to stress reveal shared evolutionary trends between *Tetrahymena utriculariae* and its algal endosymbiont, *Micractinium tetrahymenae*

Kelly J¹, Carlson D², Reuter M¹, Sommershof A¹, Adamec L³, Becks L¹

¹University Of Konstanz, ²Stony Brook University, ³Institute of Botany of the Czech Academy of Sciences

POSTER SESSION 2 - P02.110, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The evolution of intracellular endosymbiosis marks a major transition in the biology of the host and endosymbiont. Yet, how adaptation manifests in the genomes of the participants remains relatively understudied. To investigate this question, we sequenced the genomes of *Tetrahymena utriculariae*, a species-specific commensal of the aquatic carnivorous bladderwort *Utricularia reflexa*, and its intracellular algae, *Micractinium tetrahymenae*, and two of their closest relatives using long-read DNA sequencing. We discovered that the *T. utriculariae* genome experienced an expansion in a protein family bearing the TLD domain, which was also found to be under strong purifying selection, identifying it as a candidate for being an adaptive response to oxidative stress resulting from the physiology of its

endosymbionts. We discovered that the *M. tetrahymenae* genome is expanded relative to congeners and contains a greater number of rapidly expanding gene families. These were enriched for Gene Ontology terms relevant to cellular responses to stress and stimulus, and the regulation of intracellular signal transduction. Using a comparative transcriptomic analysis of *M. tetrahymenae*, we discovered that the algal genes that are differentially expressed between symbiotic and free-living states were enriched for pathways that evidence shifts in energy generation and storage and cellular protection. Together, our results elucidate the axes along which the participants must adapt in this young endosymbiosis and, in particular, identify adaptation to stress as a shared coevolutionary trend.

Host species identity and phyllosymbiosis as the main evolutionary and ecological drivers of gut microbiota in wild rodent species in the Yucatán peninsula

Borja-martínez G¹, Vázquez-Domínguez E¹, Falcón Álvarez L¹

¹Institute of Ecology

POSTER SESSION 2 - **P02.115**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: The host-microbiome association is considered a coevolutionary process in which the microbiome provides important functions for host development, physiology, and health. However, the ecological and evolutionary forces shaping the diversity and structure of the bacterial communities that form the microbiome are still being elucidated. Microbiome studies in rodents suggest that the bacteriome is mainly shaped by diet, geography, host genetics, environment, and phyllosymbiosis. The latter refers to the eco-evolutionary pattern in which closely related host species often tend to have more similar microbiota. We assessed the composition of gut microbiota in six rodent species from three geographic regions across the Yucatán peninsula, Mexico. We aimed to determine if the host species identity and phyllosymbiosis are the primary drivers of gut microbial structure and diversity. We predict that each host species would have an overall distinct bacterial community sharing the same environment.

Materials and methods: We amplified and sequenced the 16S rRNA V4 gene in 63 rodent individuals and evaluated the contribution of host species identity, phylogenetic relationships, habits, and geography to the rodents' gut microbiome. For this, we quantified Hill numbers for alpha diversity and assessed differences in abundance of microbial taxa among host species. We used a random forest approach to analyze, identify, and classify the bacterial families between rodent species based on their similarity. We also estimated beta diversity with phylogenetic and non-phylogenetic estimators and evaluated differences among host species. We applied Blomberg's K and Pagel's λ tests to determine whether microbial diversity, phylogeny and beta dispersion have a phylogenetic signal. Finally, we performed a Mantel test between host phylogenetic distances and bacterial community dissimilarity.

Results: Significant differences ($p < 0.01$) among rodent species were found for amplified sequences

variants (ASVs), where *Ototylomys phyllotis* and *Sigmodon toltecus* showed the highest richness and *Peromyscus leucopus* the lowest across all taxonomic levels. No differences were observed for common and dominant microbial taxa for any taxonomic category. The host species had differential abundance, where Lactobacillaceae was highly abundant in *Peromyscus yucatanicus*, Christensenellaceae predominating in *P. leucopus*, Muribaculaceae in *O. phyllotis*, Ruminococcaceae in *Heteromys gaumeri*, Desulfovibrionaceae in *Oryzomys couesi*, and Staphylococcaceae in *S. toltecus*. Random forest (RF) classifier was able to categorize the individuals into their respective species with high accuracy (94%), indicating that host species determine microbial composition. Phylogenetic distances (Unifrac) showed significant composition differences between *P. yucatanicus* and *O. phyllotis* and between *P. yucatanicus* and *S. toltecus*. Finally, we found weak but significant phylogenetic signals on microbial richness, common species, beta dispersion, and beta diversity.

Conclusions: Our results show that host species identity and phyllosymbiosis are the main mechanisms driving microbiome dissimilarity across the rodent species studied. Specifically, that gut bacterial assembly dissimilarity increases with host phylogenetic distance, which could imply reciprocal adaptation between microbiota and host. Notably, host phylogeny constrains interspecific composition but not abundance; we found that the main gut microbiota differences between rodent species were based on the abundance of eight bacterial families, which are associated with distinct habitats, diets, and metabolic functions. For instance, rodents with more specialized habits like *Ototylomys phyllotis* (semi-arboreal and folivorous) have higher bacterial diversity. The multispecies approach allows us to make inferences about their evolution and ecology.

Intracellular signaling in proto-eukaryotes evolves to alleviate regulatory conflicts of endosymbiosis

von der Dunk S¹, Hogeweg P², Snel B²

¹University Of Oxford, ²Utrecht University

*POSTER SESSION 2 - **P02.112**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM*

The complex eukaryotic cell resulted from a merger between simpler prokaryotic cells, yet the role of the mitochondrial endosymbiosis with respect to other eukaryotic innovations has remained under dispute. To investigate how the regulatory challenges associated with the endosymbiotic state impacted genome and network evolution during eukaryogenesis, we study a constructive computational model where two simple cells are forced into an obligate endosymbiosis. Across multiple in silico evolutionary replicates, we observe the emergence of different mechanisms for the coordination of host and symbiont cell

cycles, stabilizing the endosymbiotic relationship. In most cases, coordination is implicit, without signaling between host and symbiont. Signaling only evolves when there is leakage of regulatory products between host and symbiont. In the fittest evolutionary replicate, the host has taken full control of the symbiont cell cycle through signaling, mimicking the regulatory dominance of the nucleus over the mitochondrion that evolved during eukaryogenesis. Thus, our modeling approach contributes to an integrated view of the eco-evolutionary dynamics of endosymbiosis and the transition towards individuality of the symbiotic partnership.

An evolutionary mosaic of proteins mediates metabolic integration in transient kleptoplasts in the euglenozoan *Rapaza viridis*

Garcia Cunchillos I¹, Kashiya Y², Karnkowska A¹

¹Institute of Evolutionary Biology, Faculty of Biology, Biological and Chemical Research Centre, University of Warsaw, ²Department of Applied Chemistry and Food Science, Faculty of Environmental and Information Sciences, Fukui University of Technology

MEETING ROOM 131, August 19, 2025, 11:00 AM - 1:00 PM

Acquired phototrophy is widespread among various eukaryotic lineages and involves different secondary endosymbioses of photosynthetic, plastid-bearing eukaryotes. While most of these secondary photosymbioses preserve the wholeness of the photosynthetic endosymbiont, others only retain determined endosymbiont organelles. To the extreme of this range, in kleptoplastidy, the host subtracts solely the plastids from the endosymbiont, which remain only temporarily functional and thus require constant replacement. While kleptoplastidy is broadly present among eukaryotes, we only know about four examples in which the host, at least partially, controls kleptoplast activity with nucleus-encoded proteins. The euglenozoan *Rapaza viridis* is a unique model of obligatory kleptoplastidy, showing high specificity for the plastids of one particular green alga, *Tetraselmis* sp. NIES-4478, and thriving only in the presence of both light and prey algae. Furthermore, transcriptomic data revealed extensive targeting of nucleus-encoded proteins to the kleptoplast, suggesting an extraordinary molecular integration. Here, we study the molecular integration of the kleptoplasts in *Rapaza viridis* metabolism by predicting the plastid proteome from the *Rapaza viridis* transcriptome and reconstructing plastid pathways. We combine this information with the plastid proteomes of eight photosynthetic euglenozoans with permanent plastids predicted from newly generated and publicly available transcriptomes. We further study the evolutionary origin of over 200 detected proteins involved in seven putative plastid metabolic pathways, the photosynthetic machinery, and transporter elements.

The nucleus of *Rapaza viridis* encodes kleptoplast-targeted proteins involved in functions related not only to photosynthesis but also to other processes occurring in plastids,

such as carbon fixation or chlorophyll, terpenoid, and carotenoid biosynthesis. However, the completeness of these pathways is uneven, and some essential proteins are missing in the *Rapaza viridis* proteome. Phylogenetic analyses revealed further insights into the origin of these proteins, describing three different evolutionary scenarios. First, some proteins showed an unambiguous origin in the species from which *Rapaza viridis* steals the plastid, most probably acquired by endosymbiotic gene transfer. Variable divergence levels (comparing *Tetraselmis* sp. and *Rapaza viridis* sequences) revealed that the acquisition of these genes occurred at different times. The second scenario encompasses the proteins acquired from species other than *Tetraselmis* sp., either by endosymbiotic or horizontal gene transfer. In euglenozoans, nucleus-encoded proteins require a spliced leader trans-splicing pre-sequence, essential in the posterior RNA regulatory process. Remarkably, genes coding proteins in these two evolutionary scenarios showed the development of this spliced leader sequence, confirming the complete integration in the *Rapaza viridis* nucleus. The third scenario comprised a set of *Rapaza viridis* own proteins that seem to have been re-targeted to the kleptoplast in the switch to mixotrophy.

Kleptoplastidy is an advantageous model for studying mechanisms of plastid integration in eukaryotes. However, most known examples involving ancestrally-lacking-plastids species do not usually detect significant targeting of nucleus-encoded proteins, suggesting limited molecular integration. Comparatively, *Rapaza viridis* kleptoplasts show substantial metabolic integration, standing out as a new model to investigate the early and intermediate stages of plastid integration and opening a new gate to experimental research in this field.

Interplay of HGT and targeting during the chromatophore organellogenesis in Paulinella

Bernabeu M^{1,2}, Gabaldón T^{1,2,3,4}

¹Barcelona Supercomputing Center, ²Institute for Research in Biomedicine, ³Catalan Institution for Research and Advanced Studies, ⁴Centro de Investigación Biomédica En Red de Enfermedades Infecciosas

MEETING ROOM 131, August 19, 2025, 11:00 AM - 1:00 PM

Horizontal Gene Transfer (HGT) is the movement of genes between genomes apart from sexual recombination. Eukaryotic and prokaryotic co-occurrence, symbiotic relationships or phagotrophic lifestyles can modulate HGT. The chromatophore is a photosynthetic organelle in some Paulinella species, it derives from an endosymbiotic event that occurred more recently than the origin of chloroplasts. Thus, Paulinella represents a crucial clade to understand organellogenesis. HGT events have been previously described between Paulinella and diverse bacteria. However, an in-depth characterisation of the donors and a temporal framework for transfer highways in

these species is still missing. Here, we studied the origin of the gene families in the species Paulinella micropora, assessed HGT patterns, and inferred the relative age of the transfers from non-eukaryotic clades to evaluate whether HGT happened in distinguishable waves. We observed a high diversity of donors, which transferred genes in a continuum rather than specific waves. Functional and subcellular localization analyses show that the majority of the chromatophore-targeted proteins have a vertical origin. Based on this and other results, we propose a model for the origin and early evolution of the chromatophore.

Stepwise genome evolution from a facultative symbiont to an endosymbiont in the N₂-fixing diatom-Richelia symbioses

Grujic V^{1,2}, Mehrshad M², Vigil-Stenman T¹, Lundin D³, Foster R¹

¹Department of Ecology, Environment and Plant Sciences, Stockholm University, ²Department of Aquatic Sciences and Assessment, Science for Life Laboratory, Swedish University of Agricultural Sciences,

³Department of Biology and Environmental Science, Linnaeus University, Kalmar, Sweden

MEETING ROOM 131, August 19, 2025, 11:00 AM - 1:00 PM

Cyanobacteria from genera *Richelia* are predominantly observed in symbiosis with diatoms, particularly in nitrogen-poor regions of the ocean. The diatom-*Richelia* symbioses represent a valuable system to study the evolution of symbiosis from free-living and facultative cyanobacteria to obligate symbionts. A unique feature of this system is the continuum of symbiont cellular integrations ranging from externally attached epibionts to periplasmic symbionts and endobionts, accompanied by corresponding patterns of genome reduction and functional gene loss. In this study, we analyzed four draft *Richelia* spp. genomes and ten environmental metagenome-assembled genomes (MAGs) using comparative genomics analyses. We observed an enrichment of insertion sequences (IS) and high numbers of pseudogenes in the genomes of periplasmic symbionts, suggesting earlier stages of genome reduction. Conversely, endobionts exhibited comparatively smaller genomes, fewer IS

and pseudogenes, consistent with advanced stages of genome degradation and increased host dependency. Pangenome analyses revealed that endobionts maintain a higher proportion of their gene clusters in the core genome, while epibionts and periplasmic symbionts possess more flexible and singleton gene clusters, indicating greater genomic plasticity. Functional comparisons with other N₂-fixing cyanobacteria, including the spheroid bodies of diatom *Epithemia*, UCYN-A/nitroplast, and *Nostoc* azollae symbiont of water ferns, showed similar patterns of metabolic gene loss. However, *Richelia* endobionts were distinguished by the specific absence of genes such as cytochrome bd ubiquinol oxidase and those required for the biosynthesis of lipid A, α -Tocopherol, biotin, and tryptophan. These losses highlight increased host dependency and a trend toward irreversible genomic reduction.

Subcellular proteomics illuminates the relationship between host and symbiont in trypanosomatid *Angomonas deanei*

Hammond M¹, Chmelova L², Puente V¹, Kuenzel N², Kumar A², Cadena L³, Pašuthová, K², Ferreira E⁴, Dowle A⁴, Mottram J⁴, Lukeš J¹, Nowack E³, Vjačeslav J²

¹Biology Centre, ²University of Ostrava, ³Heinrich Heine University Düsseldorf, ⁴University of York

MEETING ROOM 131, August 19, 2025, 11:00 AM - 1:00 PM

Kinetoplastid *Angomonas deanei* harbours a single endosymbiont of β -proteobacterial origin within its cytoplasm. This endosymbiont provides various metabolites such as heme and purines, and occupies a consistent position within the cell, undergoing coordinated replication prior to that of its host. *A. deanei* encodes seven known endosymbiont-targeted proteins (ETP), which localise to various regions of the bacterium and exert control over endosymbiont-related processes, including division. Gene loss undergone by this bacterium renders it unable to survive as a free-living organism, and it is regarded as being in a transitional state from endosymbiont to integrated organelle, like the mitochondrion or plastid.

To better clarify the relationship between both organisms, we initiated subcellular proteomics to assign localisation for the proteins encoded by each, many of which

lack any sort of functional annotation. Through our efforts, we confirm the existence of an eighth ETP and identify several other candidate proteins being targeted from the host to endosymbiont in a similar manner. We further identify a novel lateral gene transfer to the nuclear genome, encoding a protein interacting with a previously identified ETP, which regulates endosymbiont division. Finally, we proteomically characterise a 'contact site' between the bacterium and host organelles, primarily consisting nuclear membrane and endoplasmic reticulum constituents, which seemingly serves to maintain the endosymbiont in its characteristic position. Our data suggests the employment of over a hundred proteins by *A. deanei* to maintain this complex relationship and offers insight into the nature of endosymbiotic events seen across protistan organisms.

S20 - Evolutionary biology meets genetic pest control

Epistasis among fungicide resistance mutations

Biočanin L¹, Kleppe A², Kronholm I³

¹University of Jyväskylä, Department of Biological and Environmental Science, ²University of Jyväskylä, Department of Biological and Environmental Science, ³University of Jyväskylä, Department of Biological and Environmental Science

POSTER SESSION 1 - P01.238, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Fungicide resistance poses a significant threat to agricultural productivity, as fungal pathogens increasingly adapt to withstand fungicides. Understanding the genetic interactions, or epistasis, among fungicide-resistant mutations is crucial for predicting the

evolutionary trajectories of resistant strains and informing sustainable control strategies. In this study, we investigated the epistatic interactions among resistance mutations by evolving 20 lines of the filamentous fungus *Neurospora crassa*, with 10 lines for each mating type, under incrementally increasing concentrations of the fungicide tebuconazole, culminating at 2 µg/ml. Following the evolution experiment, we will sequence the

genomes of the evolved lines to identify mutations conferring resistance. Crosses will be then made between lines harboring distinct resistance mutations to evaluate the extent to

which epistasis influences the fitness of resistant strains. By quantifying growth rate variations among offspring with different combinations of resistance mutations, this research aims to clarify whether epistasis hinders, enhances, or has a neutral effect on fungal growth rate in the context of fungicide resistance. These findings will contribute to our understanding of resistance dynamics and provide insights into the potential limitations and strengths of resistant fungal populations under ongoing selective pressures.

Implications of intraspecific variation in genes determining host plant use in a generalist herbivore

Villacis Perez E¹, Rooker C¹, Schrama X¹, Kant M¹

¹University of Amsterdam

POSTER SESSION 3 - **P03.033**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The interactions between plants and herbivores fuel an evolutionary arms race, evidenced through ecological and molecular scales. Anti-herbivory strategies of plants impose pressure on herbivores to evolve counter adaptations. In agricultural ecosystems, pest control strategies, such as chemical control and breeding of resistant plant varieties, are constantly compromised by pest adaptations due to natural selection. Knowledge about the adaptability of pests can help prevent pest formation, before the need to control pest outbreaks arises. We investigate the molecular interactions between the generalist mite *Tetranychus urticae*, a notorious agricultural pest, and several of its plant hosts. During feeding, mites inject salivary proteins into their hosts. These proteins interact with targets in the plant, subsequently inducing or suppressing plant defenses against herbivory. Our aim is to explore how intraspecific variation in mite genes coding for salivary proteins affects their ability to interact with plant targets, in order to estimate how these protein interactions promote adaptation to novel hosts. We conduct a comprehensive field

effort to sample mite individuals from different host plant species across the dune ecosystem of the Netherlands and Belgium, in order to identify natural variants of a spider-mite specific family of genes encoding for salivary proteins, called “SHOT”. We isolate DNA from individual mites and obtain long-read sequences of the SHOT2 clade, which consists of four paralog genes residing in a 25kb region of the spider mite genome. Using an array of protein-protein interaction techniques, we identify a target of a SHOT2 protein and established that in absence of this plant target, mite fitness decreases. We assess to which extent different SHOT variants (de)stabilize the interaction with different target orthologs, and how this relates to mite fitness using SHOT2-mutant mite lines. We provide empirical evidence of the relationship between allelic variation in herbivore genes and plant targets that determine host compatibility, which is crucial for data-driven crop management strategies.

Insect-plant interactions at cell-type resolution: insights from the green-veined white

Medina Jiménez B¹, Schneider K¹, Wheat C¹

¹Stockholm University

POSTER SESSION 1 - **P01.239**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Phytophagous insects such as the butterflies have evolved detoxification genes and gene families in response to the chemical defenses of their host-plants. In particular, pierinae butterflies (Lepidoptera: Pieridae) are well known to resist the glucosinolate (GSL) defenses of their host-plants belonging to the cabbage family (Brassicales) and are optimal research organisms for plant-insect interaction studies. Although transcriptomics has allowed the discovery and characterization of several gene families involved in detoxification, little is known about their spatio-temporal expression across cell lineages. Here we applied single-nuclei RNA sequencing (snRNA-seq) to characterize the cell types present in the midgut of *Pieris napi* larvae that were fed two Brassicales host plants. Our goal was to search for differentially expressed genes due to the diets and to assess their expression patterns across identified cell lineages/types. **Materials and Methods:** *Pieris napi* larvae were reared on either horseradish (*Armoracia rusticana*) or watercress (*Nasturtium officinale*) leaves. At 4th instar, midguts were extracted and flash frozen to be processed for snRNA-seq following 10x Genomics technologies and protocols. Short sequencing reads were mapped to the *P. napi* reference genome and the resulting gene expression matrix was filtered and processed for downstream analysis using the bioinformatics tool Seurat, which clusters the cells according to their transcriptomic profiles.

Results: From our cell transcriptomics analysis we identified intestinal stem cells as well as the lineages leading to enterocytes and enteroendocrine cells. In addition, we identified cells from the immune system and the midgut muscle and neuromuscle. We discussed the reliability of the proposed

midgut cell type markers from the fruit fly *Drosophila melanogaster*, the silk moth *Bombyx mori* and the fall armyworm *Spodoptera frugiperda*, and then assessed their applicability to pierinae butterfly mid-late stage larvae, and described a series of candidate marker genes found in our dataset. Regarding differential gene expression caused by diet treatment, we found that major allergen (MA), a gene coding for nitrile-specifier proteins (NSPs) known to confer resistance to GSL, was highly upregulated across all cell clusters in watercress-fed samples (WC), predominantly in those identified as enteroblasts. However, this gene is strikingly downregulated in all clusters from the horseradish treatment (HR). This diet-derived differential expression pattern is also observed for several cytochrome P450-like coding genes, known for their role in insecticide metabolism, and other known detoxification gene families, namely, UDP-glycosyltransferases (UGTs), sulfotransferases, carboxylesterases and glutathione S-transferases (GSTs). Interestingly, some GST-like genes show an opposite expression pattern (high in HR, low in WC). While most of these detoxification genes are significantly upregulated in WC compared to HR and their activity appears to be general regardless of cell lineage/type, some genes show cell type specific expression in one or the other treatment. This is also observed for certain genes with no known role in detoxification.

Conclusion: Our findings provide a plethora of candidate genes for midgut cell-type identification as well as cell resolution insights into the expression and role of detoxification gene families showing the benefits of applying snRNA-seq in insect-plant interaction research.

Integration of databases and High-Performance Computing in Dengue Virus research: Advances in the development for RT-LAMP detection

Cadena-Caballero C¹, Ortiz-Salamanca N¹, Cangrejo-Useda Y¹, Vera-Cala L², Barrios Hernández C³, Martínez-Pérez F¹

¹Laboratorio de Genómica Celular Aplicada (LGCA) del Grupo de Investigación Computo Avanzado y a Gran Escala (CAGE), Universidad Industrial de Santander., ²Grupo de Investigación en Demografía, Salud Pública y Sistemas de Salud (GUINDESS), Departamento de Salud Pública, Universidad Industrial de Santander., ³Grupo de Investigación en Computo Avanzado y a Gran Escala (CAGE), Universidad Industrial de Santander

POSTER SESSION 1 - P01.235, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Introduction: Dengue virus (Orthoflavivirus denguei) is a single-stranded RNA-positive flavivirus (~11 kb) with four antigenically distinct serotypes. Its transmission by mosquitoes, mainly *Aedes aegypti* and *A. albopictus*, explains the 14 million global cases and 7,700 deaths reported in 2024. In Colombia, an increase of patients with Dengue symptoms was observed in 2023 and, for the department of Santander, in 2024. Therefore, the National Institute of Health of Colombia invited to improve the methods of its diagnosis, for which it is critical to optimize molecular diagnostic methodologies such as ELISA, RT-PCR and RT-qPCR, that will always be limited by gene drift and selective pressures on the genomic regions used for virus identification. Another option is RT-LAMP, that has the advantage of simplicity and speed due to its thermo-dependence and colorimetric readout. However, it also requires primers designed under rigorous evolutionary parameters to minimize false negatives. This study proposes an integrative bioinformatics protocol for RT-PCR/RT-LAMP oligonucleotide design based on evolutionary patterns of the virus in South America. **Material and Methods:** Complete Dengue genomes were collected from the GenBank database up to December 2024. With an R algorithm optimized for High-Performance Computing (HPC), sequences with ambiguous regions (>5% N), low quality (Phred <30) and indeterminate regions (-) were filtered out. The final database included sequences from South America. The alignments were performed in MAFFT with the parameters of the evolutionary model of DNA loss. Consensus sequences were generated with BioEdit: (1) majority consensus (nucleotide frequency >70%); and (2) degenerate consensus (IUPAC code for polymorphisms with frequency >10%). RT-PCR primers were designed with the OligoAnalyzer tool, while RT-LAMP primers were designed with the NEB LAMP Primer Design Tool

(parameters: Tm=65±2 °C, length 18-22 nt, GC=30-70%), and the in silico specificity was validated through BLASTn.

Results: 7,490 complete Dengue genomes were obtained, the alignment by serotype showed a world regional distribution. Therefore, to determine the previous pattern, 219 sequences were selected that met the selection criteria: Colombia, Ecuador, Panama, Venezuela, Peru and Brazil. The consensus sequence generated by IUPAC showed a high nucleotide variability. However, the majority nucleotide consensus (>70% frequency) identified 11 conserved genomic regions within the ORF. These regions were used to design 8 RT-LAMP primer sets, 2 per serotype, DENV-1 to DENV-4. In silico validation by BLASTn showed that the primers presented differential coverage between serotypes (> 95%), with no cross-reactivity with human genomes or other pathogens. Additionally, primers for real-time RT-PCR that target conserved segments were proposed and corroborate the quality regions.

Conclusion: The integration of HPC applied to RT-LAMP primer design for the identification of conserved genomic regions of dengue virus serotypes allows for the design of oligonucleotides and hybridization parameters for viral genetic RT-LAMP, which will reduce false-negative results. Furthermore, complementing the results with RT-PCR and the characterization of new viral genotypes with Next-Generation Sequencing will contribute to global and regional epidemiological surveillance by identifying emerging viral variants. The authors are grateful to the Internal Call for Research, with Cash Contribution of the E.S.E. Hospital Universitario de Santander 2024. Mobility Program and Project No. 8078 of Vicerrectoría de Investigación y Extensión of the Universidad Industrial de Santander, for funding this research.

Limited spatial propagation of quorum-drive systems through wave pinning

Doulcier G¹, Kläy L², Débarre F^{1,3}

¹Sorbonne Université, ²Université de Brest, ³CNRS

POSTER SESSION 1 - **P01.242**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Artificial gene drive alleles are engineered to bias their own inheritance, and can help rapidly spread a desired trait through a target population. Spatial confinement is essential to restrict gene drive spread to target populations and prevent unintended ecological impacts. It can be obtained via the use of a bistable system, in which an allele can only spread if introduced above a threshold frequency, and if the migration rate is low enough. Bistability is produced by a fitness valley, which can be caused by heterozygote disadvantage or the use of toxin-antidote systems. In a metapopulation, the spatial spread of a bistable drive allele can be limited. This phenomenon is called "wave-pinning" in traveling wave models for spatial invasion. However, predicting when waves will stop is difficult. Here, we first

adapt existing methods for wave pinning prediction in bistable one-locus heterozygote systems. We then extend the study to a two-locus four-allele drive system. We show that wave pinning appears as a result of limited dispersal. We also find that wave pinning can artefactually happen as a consequence of changing the precision of the discretization lattice in the numerical simulation of partial differential equations, and we provide an upper bound on lattice size to prevent this numerical artifact. Relying on incorrect numerical models to inform gene drive policies could have far-reaching consequences on natural populations; our results describe a way to avoid incorrect predictions of spatial confinement of introduced gene drive alleles

Optimizing biological pest management by investigating the genetic basis of parasitoid chemical communication systems

Büllesbach J¹, Sun W², Gadau J²

¹Technical University Of Munich, ²University of Münster

POSTER SESSION 1 - **P01.244**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Parasitoid wasps are increasingly recognized as effective biological control agents in integrated pest management, offering sustainable alternatives to chemical pesticides with benefits for human health, agricultural productivity, and ecosystem integrity. A detailed understanding of their pheromonal communication—central to reproduction and species interactions—is essential for maximizing their efficacy as biological control agents.

The *Nasonia* species complex, a powerful model system in both evolutionary and chemical ecology, offers key insights into how complex mating signals evolve and function. In *Nasonia*, females produce species-specific cuticular hydrocarbon (CHC) profiles that serve as sex pheromones, guiding male courtship and mating behavior. We identified specific methyl-branching patterns in these CHCs as critical components of sexual signaling and functionally characterized three fatty acid synthase genes responsible for their biosynthesis. These genes maintain both overall CHC profile integrity above male detection thresholds and the specific structural features linked to sexual

attractiveness—directly connecting genetic variation to mating success.

Our findings demonstrate how genetic information can be translated into ecologically relevant chemical signals, revealing a relatively simple genetic basis for sexual attractiveness. They also provide rare insights into the potential evolution of sexual communication and its role in reproductive isolation and speciation. Building on this foundation, we are now investigating the chemosensory mechanisms underlying pheromone perception in the *Nasonia* model system, which is exceptionally well-suited to uncover these understudied processes as well to obtain a more holistic view of the delicate interplay between sender and receiver.

By elucidating the genetic and sensory basis of pheromone communication, our research advances both fundamental evolutionary biology and the applied science of biological pest control. This integrative approach holds promise for optimizing mass-rearing conditions and sustainability over multiple generations of parasitoids like *Nasonia*, contributing to more efficient, eco-friendly strategies for sustainable agriculture.

Polymorphism Of The Ovine-Mhc Drb1 Exon 2 Gene And Its Association With Tick Infestation In Damara Sheep At Neudamm Farm, Namibia

Amushendje T¹, Paulus F¹

¹University Of Namibia

POSTER SESSION 1 - **P01.237**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The objective of this study was to identify allelic variation in the ovine-MHC DRB1 exon 2 gene and investigate the relationship of the polymorphism to external tick infestation in Damara sheep at Neudamm farm. The study also investigated sex and season effects variation in tick numbers. Ninety sheep (n=64 female and 26 male) were used. The ticks were counted twice in two seasons, wet and dry. Blood samples were collected in four mL K2E-EDTA anti-coagulant vacutainer tubes via jugular vein. Genomic deoxyribonucleic acid (gDNA) was extracted from blood using ZR Zymo kit (Zymo Research, CA, USA). Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP) method was used to identify genetic variation in the MHC DRB1 exon 2 gene. Chi-square test was used to test for association at 5% level of significance and to determine

the significance ($P < 0.05$) of mean variations of tick numbers between seasons. Three banding patterns, representing three genotypes, A1A1 (30%), A1A2 (40%), A2A2 (30%) were observed. A1A1 genotype had high tick counts than the other genotypes. However, this was not statistically significant. Similarly, there was no significant difference between the male and female tick counts ($P > 0.05$). Tick numbers differed significantly between the wet and dry seasons ($P < 0.05$). The genotypes and allele frequencies of the gene and number of ticks were in Hardy-Weinberg equilibrium (HWE). These preliminary results may be used for future genetic and conservation research to identify genetic markers linked to tick infestation in Damara sheep.

Key words: Damara sheep, PCR-RFLP, Polymorphism, Restriction enzyme, BsaHI.

Spatial soft-sweeps: a means to jointly estimate recent demography and migration in *Anopheles gambiae* from insecticide resistance loci

Khatri B¹, Fernandez Perez M, Burt A

¹Imperial College London

POSTER SESSION 1 - **P01.243**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Predicting the response of populations to genetic interventions, and ecological changes in general, require a characterisation of their population size and migration rates, as these determine the complex spatio-temporal dynamics of populations — for example, chasing dynamics seen in response to suppression gene drives (North et al, BMC Biol, 2019, 2020 and Champer et al, Mol Ecol, 2021) — and ultimately the probability and duration of resistance (Khatri & Burt, PNAS, 2022).

Spatial soft sweeps give an opportunity to probe the recent evolutionary history of natural populations. We recently developed a robust method to estimate the recent effective population size from the number of independent origins of a positively selected mutation (Khatri & Burt 2019, MBE), assuming a panmictic population. However, in practice, local migration will give rise to a complicated spatial structure of origins, which may leave a fingerprint for its inference.

Here we develop computationally efficient simulations of spatial soft sweeps, which go

beyond the assumption of allelic exclusion (Ralph & Coop, Genetics, 2010; Paulose 2019). By a judicious choice of summary statistics, we show that these simulations can jointly estimate population size and diffusion constant, using a combination of ABC and machine learning approaches.

We apply this method to the *kdr* insecticide resistance mutation in the *Vgsc* locus in natural populations of *Anopheles gambiae*, across the whole range of sub-Saharan Africa, to give for the first time a continent wide picture of their recent evolution. Our results suggest effective population sizes of order 100s millions and diffusion constants of order 100s of km²/generation. Future work will focus on refining these estimates in light of seasonal variation in demography and the role of non-local migration.

These results will inform future stochastic spatio-temporal modelling of suppression drives to more accurately predict the response of natural *Anopheles* populations to these genetic interventions.

Sting Operation: Population Genetics of Yellow Legged Hornets (*Vespa velutina*) Using Single Nucleotide Polymorphisms

Griffin S^{1,2}, Jones E², Haynes E², Jensen E¹

¹Newcastle University, ²Fera Science Ltd.

POSTER SESSION 1 - **P01.236**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Yellow legged hornets (*Vespa velutina*) are invasive insects which pose a threat to native insects, biodiversity and apiculture. They were thought to have first been introduced to France in 2004 in a shipment of pottery from Asia. In the following years, these insects have rapidly spread across Europe to countries such as the UK, Spain, Portugal, Italy, the Benelux countries, and Germany.

In the UK, there have been 147 laboratory confirmed sightings since 2016, including 110 nests. The government is currently taking an eradication approach, where each identified nest and individual are destroyed. It is thought that the majority of hornets intercepted in the UK are hitchhikers from the continent but there is suspected local breeding taking place as well. The UK government also makes use of genetic markers (microsatellites) to inform management. These markers are used to assign any lone hornets caught in traps away from the nest to any incepted nests already located. If the individual cannot be assigned it can indicate the presence of a new nest within that area suggesting the need for increased monitoring and trapping. The microsatellites markers are also used to

determine the number of males have bred with the queen to produce the nest.

Microsatellites however have limited resolution for kinship analysis and make use of older sequencing technologies. Therefore, a more precise method involving the use of high-density genetic markers, such as single nucleotide polymorphisms (SNPs), and next generation sequencing techniques (Illumina sequencing), could provide a higher resolution solution. Single nucleotide polymorphisms are variations at single base position in the DNA. Hundreds of SNPs can be amplified within a Genotyping in Thousands by Sequencing (GT-seq) assay (Campbell et al. 2015) to have the potential to genotype multiple individuals simultaneously at lower costs and with higher resolution. This study developed a panel of hundreds of SNP markers which were sequenced using Illumina MiSeq to analyse UK nests and individuals from 2016 - 2024 and comparing their genetics to European samples (Jersey, France, Benelux, Germany, and Portugal), improving our understanding of hornet spread and kinship relationships between nests aiding in management strategies within the UK and beyond.

Thermal adaptation amplifies increases in insect crop damage from climate warming

von Schmalensee L¹, Bodeci G², Lancaster L², Berger D¹

¹Uppsala University, ²University of Aberdeen

POSTER SESSION 1 - **P01.246**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Climate warming can influence insect populations through direct effects on physiological processes, like those governing development, growth, and reproduction. Such plastic responses are projected to increase crop damages by insects under future warming scenarios. However, previous work has largely overlooked the important role of adaptive evolutionary responses of insect pests facing climate change.

Here, we evolved replicate lines of the seed beetle pest *Callosobruchus maculatus* under 23 °C, 29 °C (“ancestral”), and 35 °C to assess evolutionary potential in temperature-dependent reproductive output, development rate, and growth rate. To estimate future population growth and crop damage rates across seasons, we integrate evolved reaction norms with diverse realistic and temporally high-resolved thermal regime simulations under different warming scenarios. In line with previous research, we find that plastic responses on average increased crop damage by approximately 20% per degree of warming. Crucially, however, we find that projected crop damage is on average an additional 64% higher in the warm-adapted selection lines than in the ancestral lines. This increase from only 10 years of thermal adaptation in the laboratory corresponds to that caused by a mean climate warming of ~3

°C. Additionally, by fixing reaction norms for certain traits to the ancestral state and allowing others to take on the evolved state, we identify counter-gradient shifts in maximum growth rate and reproductive output as the main culprits behind the increased crop damage rates in the warm-adapted lines.

Moreover, we show that diurnal and seasonal temperature variability are crucial for understanding the dynamics of future insect populations due to the nonlinear and asymmetric nature of thermal reaction norms. For example, already warm sites may become inhospitable in summer due to daytime extremes exceeding thermal limits. However, these losses may be offset by earlier springs and prolonged falls, extending the growth season. Studies fixing the growth season to a certain period of the year might therefore underestimate crop damage increases in warm climates.

In summary, we show that evolutionary responses to high temperatures are likely to amplify climate-driven increases in crop damage beyond previous estimates. Our results highlight the need for pest managers and risk analysts to account for evolutionary change and natural thermal variability at relevant regional scales for effective forecasting and control of future pest populations

Transcriptional profiles of the fish parasite *Neoechinorhynchus agilis* (Acanthocephala) emphasize energetic stress in males and high cell-division activity in females

Cozzarolo C¹, Vasilikopoulos A^{2,3}, De Thier O², Hagemann L¹, Dezfuli B⁴, Van Doninck K², Herlyn H¹

¹Johannes Gutenberg Universität, Institute of Organismic and Molecular Evolution, ²Université Libre de Bruxelles, Research Unit of Molecular Biology and Evolution, ³University Hospitals Leuven, Centre for Human Genetics, ⁴University of Ferrara, Department of Life Sciences & Biotechnology

POSTER SESSION 1 - **P01.240**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Acanthocephalans are parasitic worms with a complex life cycle consisting of a larval phase in a mandibulate arthropod and a reproductive phase in a gnathostome vertebrate. They present peculiar features, such as the ability to alter their intermediate host's behavior, thereby increasing their transmission probability, and the ability to accumulate heavy metals from the aquatic environment, lowering their concentration in fish hosts. In addition, these helminths can be pests in South American aquacultures. Although they make excellent models for the study of host manipulation and bioaccumulation, as well as of the evolution of parasitic lifestyle (e.g. loss of digestive tract), molecular data is scarce, and, to date, only one nuclear genome has been published. Overall, transcriptional bases of most aspects of the acanthocephalan life cycle are vastly unknown. Our contribution to filling this gap involves the de novo assembly of a nuclear draft genome and of the transcriptome of *Neoechinorhynchus agilis* (Eoacanthocephala) worms extracted from thinlip mullets' intestines. We conducted

differential expression analyses to compare male and female transcriptional profiles, as well as of worms of different sizes, to gain insight into the gene expressional background of maturation and reproduction in these parasites. Overall, male-biased transcripts were annotated with ontologies associated with energy metabolism, cell motility, and microtubules, suggesting male competition and sperm production. Genes related to response to stimulus and to stress were also male-biased, especially in the smallest worms, potentially illustrating the arrival of young individuals searching for a favorable position in the intestines. Gene ontologies referring to transcription, cellular division, development and adhesion, and DNA damage response were over-represented in female-biased genes, congruently with massive egg production and embryo development. Finally, we highlight fifteen genes the expression of which shows a linear correlation to size in both males and females and have human homologs involved in cancer, evidencing their importance in development and their relevance as potential targets for pest control.

Assessing the role of mitonuclear and genotype-by-environment interactions for the Trojan Female Technique in pest biocontrol

Vlajnić L¹, Savković U², Budečević S², Đorđević M²

¹Faculty of Biology, University of Belgrade, ²Institute for Biological Research "Siniša Stanković", National Institute of the Republic of Serbia, University of Belgrade

MEETING ROOM 118+119, August 18, 2025, 10:30 AM - 12:30 PM

The seed beetle (*Acanthoscelides obtectus*) is a globally distributed pest affecting common beans and various legume species. It feeds on seeds and causes considerable damage to stored products, resulting in substantial economic losses. Currently, insecticides are mainly used to control this species. However, the detrimental effects of these chemicals on the environment and non-target species, as well as the evolution of resistance, necessitate the development of safer and more specific biocontrol methods.

One such method is the recently proposed Trojan Female Technique (TFT), which leverages the evolutionary phenomenon known as the Mother's Curse. This phenomenon predicts the accumulation of male-only harming mutations in the mitochondrial genome due to its matrilineal inheritance. The release of Trojan Females - females carrying naturally occurring mitochondrial genotypes (mitotypes) that negatively impact male reproductive potential - facilitates self-sustaining transgenerational population suppression. A candidate TFT mitotype that induces male

subfertility has recently been identified in seed beetles.

However, a crucial criterion for the successful application of TFT is that the TFT mitotype must render males subfertile across a range of nuclear and environmental backgrounds, such as different temperatures. To investigate this, we tested the effects of the candidate TFT mitotype (MG3b) and two control mitotypes (MG1a and MG1d) on male and female fertility in three different nuclear backgrounds and under two temperature regimes.

Our results show that the candidate TFT mitotype at standard temperature reduces male fertility across all nuclear environments compared to control mitotypes. Conversely, MG3b males have similar reproductive performance to MG1a and MG1d males at elevated temperatures. On the other hand, female beetles carrying MG3b remain fully fertile independently of nuclear background or temperature. The results in *A. obtectus* suggest that the sex-specific effect of mitochondrial haplotype on fertility depends on complex interactions between the mitochondrial DNA, the nuclear DNA and the thermal environment.

Evaluating Wolbachia and host genetics for incompatible insect technique development in *Drosophila suzukii*

Serga S^{1,2}, MATIN M¹, Phooi C¹, Tatard C¹, Lapègue M¹, Deschamps C¹, Cesari L¹, Gautier M¹, Rode N¹

¹ CBGP, Univ Montpellier, CIRAD, INRAE, IRD, Institut Agro Montpellier, ²V.N. Karazin Kharkiv National University

MEETING ROOM 118+119, August 18, 2025, 10:30 AM - 12:30 PM

The incompatible insect technique (IIT) is a promising alternative strategy to broad-spectrum insecticides. It uses the bacteria *Wolbachia* to suppress pest populations in a more targeted and eco-friendly way. IIT is based on the phenomenon of cytoplasmic incompatibility (CI) manifested as embryonic lethality in crosses between *Wolbachia*-infected males and uninfected females. Understanding the factors that determine CI strength is important to develop IIT.

Drosophila suzukii, an invasive agricultural pest, causes major economic losses and is both a strong candidate for IIT-based control and a useful model for studying CI mechanisms.

We investigated the respective roles of *Wolbachia* and the host factors in driving CI

using *D. suzukii* strains previously shown to vary in CI strength (0-70% of CI). We found no effects of *Wolbachia* genotype on CI strength based on comparison of bacterial genomes associated with high and low CI. Furthermore, CI strength does not correlate with *Wolbachia* titers in testes. However, we found a great effect of the male host genotype on the strength of the phenotype and no effects of the female host genotype.

We emphasize that selecting a suitable host genotype is just as important as choosing the right *Wolbachia* strain. Potentially, the efficiency of incompatible insect techniques can be improved by using artificial selection of host genotypes to increase their susceptibility to *Wolbachia*-induced CI.

Gene drive dynamics in plants: the role of seedbanks

Kim I¹, Tian L^{1,2}, Chaffee R³, Haller B¹, Champer J⁴, Messer P¹, Kim J¹

¹Department of Computational Biology, Cornell University, ²Center for Genetic Epidemiology, Department of Population and Public Health Sciences, Keck School of Medicine, University of Southern California, ³Department of Molecular Biology and Genetics, Cornell University, ⁴Center for Bioinformatics, School of Life Sciences, Center for Life Sciences, Peking University

MEETING ROOM 118+119, August 18, 2025, 10:30 AM - 12:30 PM

Gene drives offer revolutionary potential for the management of problematic plant populations, such as invasive weeds and herbicide-resistant species, by rapidly spreading desired genetic alterations. Two recent studies have provided the first experimental demonstrations of engineered CRISPR gene drive systems in plants (CAIN and ClvR). However, the successful application of such systems in the field will critically depend on an accurate understanding of plant-specific life-history traits, especially seed dormancy, a ubiquitous yet frequently overlooked eco-evolutionary force. In this study, we develop the first comprehensive modeling framework for gene drives in plant populations that

incorporates a persistent soil seedbank. We show how the presence of a seedbank can significantly slow gene drive spread but also reduce the genetic load required to achieve population elimination. Furthermore, we show that seedbanks substantially increase the required introduction frequency of threshold-dependent gene drives, which could prevent establishment in some cases, yet also provide an intrinsic biosafety mechanism for confining a highly efficient drive to a target population. Our study highlights the need to incorporate seedbank dynamics into gene drive strategies to ensure more realistic predictions and successful field applications.

Mitigating resistance in gene drives using sex distortion strategies.

Vertsimakha O¹, Burt A¹, Khatri B^{1,2}

¹Imperial College London, ²The Francis Crick Institute

MEETING ROOM 118+119, August 18, 2025, 10:30 AM - 12:30 PM

Malaria remains a significant global health concern, with over 250 million cases and nearly 600,000 deaths reported worldwide in 2023. Children under the age of five are particularly vulnerable. The disease is transmitted by mosquitoes of the *Anopheles* genus, and current control measures—including vaccines and insecticides—have not proven sufficient to stop its spread. Gene drives are a promising biocontrol strategy that has the potential to significantly reduce the transmission of malaria. Genetic traits with super-Mendelian inheritance are introduced in the population enabling rapid genetic modification of the populations. However, a major limitation of gene drive technology is the evolution of resistance, which can restore population viability and undermine long-term effectiveness.

Recent studies have proposed integrating gene drives with sex distortion mechanisms, such as X-shredders, which bias offspring sex ratios toward males in drive-carrying individuals. In this work, we develop a spatially explicit stochastic model to investigate the dynamics of gene drive systems based on CRISPR-Cas9 technology

that incorporate sex distortion. We evaluate and compare the performance of various sex-distorter gene drive strategies under realistic ecological assumptions. Additionally, we contrast these with conventional single-guide RNA (gRNA) drives and multiplexed systems carrying two gRNAs, which have been proposed as a means to delay resistance.

Our results show that gene drives incorporating sex ratio distortion offer improved outcomes relative to single-gRNA designs, particularly in mitigating and delaying the spread of resistance alleles. Modelling suggests that sex distortion leads to enhanced performance in terms of probability of resistance as well as duration of the population suppression. These findings underscore the potential of sex-distorter gene drives as an effective and resilient tool for malaria vector control. Our modeling framework provides a flexible platform for evaluating drive performance under varying biological and environmental scenarios, contributing to the rational design of next-generation vector control strategies.

Out-of-locus genomic editors for efficient and localisable pest population suppression.

Willis K¹, Burt A

¹Imperial College London

MEETING ROOM 118+119, August 18, 2025, 10:30 AM - 12:30 PM

Effective control of pest populations remains a major challenge for agriculture, public health, and conservation. While currently utilised genetic control strategies—such as the release of sterile males or individuals carrying dominant lethal alleles (e.g., RIDL, fsRIDL)—have achieved some success, they often require repeated, large-scale releases, limiting scalability and applicability to species that are difficult to rear in the laboratory. Recent advances in CRISPR/Cas-based genome editing have enabled the development of more efficient genetic control methods that bias their own inheritance and impose a genetic load to achieve population suppression. However, these designs can spread throughout an entire species range, making them unsuitable when only local or temporary suppression is needed.

Here, we explore a class of self-limiting genetic control strategies that use genome

editors to increase the inheritance of deleterious alleles located elsewhere in the genome. The editor construct is inherited in a Mendelian fashion and does not drive itself, confining its impact in both space and time. Using a deterministic, discrete-generation simulation framework, we compare this strategy to existing approaches in terms of efficiency and temporal dynamics. Our results show that these editor-based strategies can achieve equivalent suppression while requiring the release of fewer modified males than traditional sterile insect techniques, with further gains achievable by targeting multiple sites or co-releasing a second construct that causes the first to transiently drive. We also propose feasible CRISPR-based molecular designs for implementing these systems. This work highlights promising alternative strategies for achieving localised, efficient, and reversible pest population suppression.

Heterosis in *Saccharomyces* hybrids: regulation of cold-adapted proteins under heat stress

Temel D¹, Gallego O¹

¹Universitat Pompeu Fabra

POSTER SESSION 1 - **P01.249**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: While interspecies hybridization is often an evolutionary dead end, certain interspecies hybrids display beneficial traits absent in either parent, a phenomenon known as heterosis. *S. cerevisiae* and the cold-adapted *S. uvarum*, can form viable hybrids despite distinct thermal limits. While *S. cerevisiae* grows up to 42°C and *S. uvarum* thrives at near-freezing temperatures, their hybrid tolerates both extremes, demonstrating heterosis. Although widely observed, the molecular basis that drives heterosis remains unknown.

This research investigates the fate of *S. uvarum* proteome in the hybrid under high temperatures, that are beyond its natural evolutionary range, exploring how it is regulated and whether it remains active in cellular processes. To reduce the complexity of the problem, we focus on a conserved cellular pathway: exocytosis, which is the secretion of cargo proteins to the plasma membrane and extracellular space. Exocytosis serves as an ideal model as it is essential for cell growth and requires regulation under changing temperatures.

Materials and methods: To investigate this, we employed a combination of genetic, imaging, and structural approaches to enable quantitative analysis of protein behaviors. Hybrid strains were constructed with fluorescently tagged exocytic proteins and allele-specific gene deletions. Live cell imaging with a precise temperature control system is used to track exocytic proteins at

different temperatures and perform in vivo protein-protein interaction analysis. Transmission electron microscopy was used to assess cellular ultrastructure under heat stress.

Results: At 37°C, hybrids continued to express exocytic proteins from both the cold- and warm-adapted parental species, opening the possibility that survival at elevated temperatures involves functional contributions from both proteomes. Supporting this idea, the deletion of essential exocytic proteins from *S. cerevisiae* allele did not impair hybrid growth at 37°C.

Long-term live cell imaging at 37°C revealed that *S. uvarum* proteins initially formed intracellular aggregates; however, functional exocytosis later resumed, indicating a restoration of function.

Conclusions: Our findings suggest that hybrids actively stabilize and maintain the functionality of thermally sensitive proteins, highlighting regulatory mechanisms underlying heterosis at the protein level. Through detailed analysis of exocytic proteins, this project aims to elucidate the specific protein interactions and modifications that enable protein function to be maintained inside the hybrid cells.

The outcome of this research could have broader implications for understanding stress tolerance at the molecular level in other organisms and may enable biotechnological applications where temperature resistance is desired.

NLR evolution and the origins of heterokaryon incompatibility genes in *Podospora*

Ament-Velázquez S¹, Saupe S²

¹Stockholm University, ²IBGC UMR 5095 CNRS University of Bordeaux

POSTER SESSION 1 - **P01.247**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Early mycological studies on model fungi demonstrated that unrelated strains can fuse vegetatively into a syncytium of genetically different nuclei called a heterokaryon. However, in many species, fusion is halted by an incompatibility reaction, which likely functions to prevent resource plundering by conspecific nuclei and/or inhibit the spread of intracellular viruses and deleterious plasmids. Although heterokaryon incompatibility is widespread, the specific genes controlling rejection (het genes) vary greatly and are species-specific. Notably, multiple het genes do share a common domain architecture resembling NOD-like receptors (NLRs), intracellular proteins that detect pathogen infections in plants and animals. Moreover, all het genes evolve under balancing selection, as polymorphism serves as a proxy for self. Given these commonalities, what is the usual ancestral state of genes recruited for heterokaryon incompatibility? Here, we explore the evolution of NLR gene families related to four het genes of the ascomycete *Podospora anserina*. By characterizing their evolution within *P. anserina* and in comparison to other *Podospora* species, we show that NLRs undergo more rapid gene turnover than random genes, while having lower GC content, higher dN/dS values, and faster evolutionary rates. A subgroup of NLRs is distinguished by superstructure-forming repeats with very high sequence identity (high internal conservation, HIC), which

evolved independently multiple times. Unexpectedly, HIC NLRs are significantly associated with transposable elements, exhibit higher nucleotide diversity, and show elevated Tajima's D values indicative of balancing selection. Furthermore, unlike typical genes, HIC NLR phylogenies do not recapitulate species relationships, instead suggesting trans-species polymorphism as expected from long-term balancing selection. Yet, this observation requires precaution. Closer inspection revealed that NLRs are preferentially involved in introgression between *Podospora* species. Some introgressed NLRs have diversity patterns consistent with selective sweeps that deplete variation, while others are bi- or multiallelic. Additionally, we identified a case of repeat exchange between distinct HIC NLR paralogs, implying that novel binding specificities may evolve through repeat shuffling, thereby increasing allelic diversity. Overall, these findings suggest that NLRs, particularly HIC NLRs, evolve under diversity-enhancing mechanisms. In line with their general immune function in other eukaryotes, NLRs frequently display genomic signatures of both Red Queen dynamics and balancing selection, with or without introgression. Hence, heterokaryon incompatibility may readily evolve from such systems, co-opting pre-existing polymorphism essential for pathogen recognition into a novel conspecific self/non-self recognition trait.

Co-ordinated regulation of gene expression inside of dikaryotic Basidiomycetes

Auxier B¹, Nygren K^{1,2}, Wösten H³, Lugones L³, Johannesson H², Aanen D¹

¹Wageningen University & Research, ²University of Stockholm, ³Utrecht University

MEETING ROOM 122+123, August 21, 2025, 2:00 PM - 4:00 PM

In Eukaryotes, mating generally occurs between two haploids leading to a diploid phase prior to meiosis. Basidiomycete fungi, particularly those that form mushrooms (Agaricomycetes), present an interesting exception to this pattern. In these fungi, mating between two haploid individuals occurs by the reciprocal donation of nuclei by both partners, followed by extremely rapid nuclear migration across both individuals. Instead of forming a diploid, a long lived dikaryotic stage with two haploid nuclei per cell is maintained. As each fertilising individual gains access to the resources accumulated by the other individual, a tension exists between the resident genome and the incoming, unrelated, fertilising genome. This tension may be increased by the occurrence of multiple, simultaneous, fertilising partners. Here we use RNA-seq of reciprocal matings between three wild isolates of the common wood-degrading fungus

Schizophyllum commune to ask if mechanisms have evolved in response to this tension, by modifying expression of genes from the fertilising, or the fertilised, nucleus. Utilizing the extremely high sequence divergence of *S. commune* we were able to distinguish expression of the alternate alleles of the vast majority (>99%) of genes. Our analyses recover significant numbers of differentially expressed genes depending on the monokaryotic or dikaryotic stage. Depending on the genetic background, there was strong correlation in the ratio of allele expression across life stages, indicating consistent dominant effects on gene expression. While there is significant evidence of differential expression within the dikaryons, we did not find a strong effect of mating role on subsequent expression. The results of this study indicate that haploid nuclei inside a basidiomycete dikaryon largely retain much of their individuality.

Fragmentation of mycelia caused loss of alleles and critical symbiotic traits in the domesticated fungus farmed by leafcutter ants

Rødsgaard-jørgensen A¹, Kokkoris V², Shik J^{1,3}

¹Section for Ecology and Evolution, Department of Biology, University of Copenhagen, ²Amsterdam Institute for Life and Environment, Vrije Universiteit, ³Smithsonian Tropical Research Institute

MEETING ROOM 122+123, August 21, 2025, 2:00 PM - 4:00 PM

In heterokaryotic filamentous fungi, specific nucleotypes (genetically distinct nuclei) may become isolated within sections of the mycelium due to random segregation. Without mechanisms to promote the distribution of nuclei within the mycelium, heterokaryons would be evolutionarily unstable.

Leafcutter ants have obligately farmed a multinucleate fungal food crop (*Leucoagaricus gongylophorus*) for millions of years. The fungus exhibits key signatures of crop domestication, including the production of specialized swollen hyphal tips called gongylidia that ants eat, and exhibiting a type of polyploidy. While the ploidy of each nucleus remains uncertain, earlier research has shown: 1) that the fungus can lose alleles when isolated from ant farmers and regrown from hyphal fragments, and 2) that this loss of alleles can cause loss of gongylidia production. These studies indicate that the fungal cultivar is a heterokaryon containing different nucleotypes.

Leafcutter farmers appear to have solved these fragmentation issues since mature colonies can have millions of ants and hundreds of football-sized subterranean fungal chambers, each containing healthy fungus established from existing fungal fragments.

We first used microsatellites (10 loci) to link the allelic profile and gongylidia production in in vitro cultures undergoing experimental fragmentation. We then sampled mature leafcutter colonies in a Panamanian rainforest to test whether these massive colonies maintained the allelic profile across

spatially distant nest chambers. Finally, we used fluorescence live imaging to visualize whether and how individual hyphae can transfer nuclei through fusions (anastomosis) within the mycelium and between fungal fragments.

While fungi readily lost both alleles and gongylidia competency when passed five times in Petri dishes without ant farmers, the fungal cultivar maintained both of these traits when actively farmed by ants in the field. The in vitro fungi obtained significantly different allelic profiles after the sequential passing, whereas this was never observed between the fungal chambers in the colonies. Specifically, gongylidia-incompetent strains had an average of 70% fewer alleles than the initial parental strain, compared to an average of 15% of alleles lost between fungal chambers in all of the ten free-ranging Panama colonies. In vitro fungi further had only 1.3 alleles per locus compared to Panamanian fungi that had 2.6 alleles per locus. Furthermore, imaging enabled us to confirm the fungal-mediated processes of nuclear movement through anastomosis.

This study demonstrates that the loss of alleles and critical phenotypic structures can occur through the fragmentation and regrowth of mycelium. Notably, this phenomenon does not occur in nature. These results point to ant-farming strategies that complement fungal cellular adaptations for maintaining nucleotype diversity, thus promoting resilient farming in this iconic mutualism.

Nuclear cooperation as a driver of evolutionary transitions in fungi

Siljestam M¹, Johannesson H¹

¹Stockholm University

MEETING ROOM 122+123, August 21, 2025, 2:00 PM - 4:00 PM

The evolution of complex life has been shaped by transitions in individuality, where distinct entities combine to form higher-level organisms. In fungi, heterokaryosis—a condition where genetically distinct nuclei coexist in the same cytoplasm—provides an ideal system to study such transitions. *Neurospora tetrasperma* is a filamentous fungus that transitioned from homokaryosis to heterokaryosis approximately one million

years ago. Using mathematical modelling within an evolutionary invasion analysis framework, we show that cooperation between two nuclear types drive this evolutionary shift. The study explore the conditions under which nuclear cooperation is favoured, providing insights into the mechanisms behind evolutionary transitions in individuality.

Premeiotic endoreplication as a compensatory mechanism in hybrid amniotes: A cellular pathway to asexuality, polyploidisation and genome stabilization

Altmanová M^{1,2}, Dedukh D², Kratochvíl L¹

¹Charles University, ²Institute of Animal Physiology and Genetics CAS

MEETING ROOM 122+123, August 21, 2025, 2:00 PM - 4:00 PM

Polyploidisation has played a crucial role in animal evolution, driving diversification in several major clades. Yet among extant amniotes, polyploidy is rare—and wherever it has become fixed, it is tightly associated with obligate parthenogenesis and hybridization. In most multicellular organisms, genetic homogeneity among nuclei ensures coordination and limits conflict. Yet in hybrid asexual vertebrates, the germline must manage profound intergenomic divergence between parental species. Our systematic comparative work of asexual vertebrates reveals a remarkably consistent cytological solution to this conflict. The overwhelming majority of obligate parthenogenetic and other asexual vertebrate hybrids employ premeiotic endoreplication, i.e. a duplication of the oogonia genome prior to meiosis, followed by a canonical meiotic process, including recombination. However, recombination occurs between sister chromatids, which typically preserves heterozygosity and maintains clonality. Nonetheless, we document that recombination contributes to structural genome reshuffling in some lineages, enabling genomic novelty even in this assumed clonal context. We confirm that over 20 independent evolutionary origins of asexual vertebrates involve premeiotic endoreplication, making it a recurrent cytogenetic strategy that facilitates asexuality in amniotes. This repeated co-option raises an intriguing question: why has this mechanism evolved so frequently? In asexual hybrids, over 95% of oocytes enter meiosis without prior endoreplication, fail to correctly pair divergent homologous chromosomes inherited from different parental species and undergo apoptosis. We propose that this massive

developmental failure triggers a compensatory mechanism, a polyploidisation in a subset of oocytes, leading to premeiotic genome duplication and restoration of homologous pairing potential, enabling meiotic progression. We hypothesize that premeiotic endoreplication functions as a compensatory response analogous to well-known adaptive somatic polyploidisation serving repair or stress response during healing and tissue regeneration. Under this view, the emergence of premeiotic endoreplication is a direct consequence of the failure to pair chromosomes in hybrid oocytes and the inherited repair compensatory mechanism connected with local polyploidisation. The mechanism of local polyploidisation in the germline of asexual hybrids not only stabilises asexuality, but it is a great preadaptation for organismal polyploidisation. The same cytogenetic strategy that allows unreduced egg formation in diploid parthenogenetic hybrids functions effectively in triploids as well. This enables incorporation of a haploid genome via sperm from a sexual relative. However, increased ploidy comes with costs: amniotes never exceed tetraploidy, and some lineages with premeiotic endoreplication do not even produce triploid lineages. We argue that germline polyploidisation in hybrid asexuals represents a key case of genetically composite development, where hybrid genomes—initially incompatible with normal meiosis—are stabilised through the recurrent co-option of ancient developmental programs. Premeiotic endoreplication deserves much greater attention in evolutionary biology as a major facilitator of genomic and reproductive innovations.

Bee gut bacteria and their arsenal: Evolution and Diversity of secretion systems

ACHEAMPONG S¹, Kwong W¹

¹Gulbenkian Institute Of Molecular Medicine

POSTER SESSION 2 - **P02.138**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The gut microbiota plays a crucial role in the physiology of the host. A stable microbiota, particularly its bacterial members, aids in nutrient metabolism, immune system modulation, and colonization resistance against pathogens. This stability is shaped by complex interactions among these members, which can be cooperative, such as metabolic cross-feeding, or antagonistic, such as competition for resources or ecological niches. A key mechanism proposed to mediate these interactions is bacterial secretion systems, specialized protein complexes that secrete effector molecules into neighboring cells or the surrounding environment to influence the stability of the microbial community. The bee gut harbors a simple and stable microbiota, which has been associated with certain secretion systems. However, the overall distribution of these systems, their association with different bee species, and their evolution have not been fully explored. Here, we show that bee gut bacteria have evolved to possess secretion systems that specialize in colonization and interbacterial competition rather than in host antagonism. Using a comparative genome analysis approach that compares the proteins of conserved components, we found that bee gut symbionts predominantly encode type V (T5SS) and type VI (T6SS) secretion systems. In contrast, the typical virulent type II (T2SS) and type III (T3SS) systems are replaced by

evolutionarily related appendages, flagella and pili, for colonization. Interestingly, we found little to no association between the presence of specific secretion systems and the bee hosts, suggesting that these systems are maintained primarily for interbacterial interactions rather than host-specific adaptation. Global-fit co-phylogenetic analyses, supported by permutation-based statistical testing, indicate significant congruence between bacterial phylogeny and secretion system phylogeny, suggesting a vertical mode of transmission for the secretion systems. Furthermore, phylogenetic analyses indicate that the evolutionary history of these systems is characterized predominantly by loss events. Our results suggest that the evolution of secretion systems in bee gut symbionts may be driven more by microbial community interactions than by adaptation to specific bee hosts, which in turn contributes to shaping a stable microbiota. We anticipate that understanding how fundamental cellular mechanisms like secretion systems evolve provides insight into the driving factors governing gut microbiota stability. Our results provide a framework for experimentally manipulating the microbiota to explore how interactions contribute to stability, as a proxy to further elucidate their role in host physiology.

Beyond abundance: Symbiont transcriptional plasticity meets host's nutritional requirements

Ayas A¹, Salem H¹, Pons I¹

¹Max Planck Institute for Biology, Tübingen

POSTER SESSION 2 - **P02.124**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Quantifying how symbionts are regulated throughout host development provides key insights into the trade-offs shaping beneficial partnerships. We explore this dynamic in the digestive symbiosis between tortoise leaf beetles (Coleoptera: Cassidinae) and *Candidatus Stammera capleta*, a gammaproteobacterium. Tortoise beetles harbor *Stammera* extracellularly within foregut symbiotic organs to facilitate folivory and in ovary-associated glands to ensure vertical transmission. *Stammera* possesses a highly reduced genome (~0.25 Mb), where it encodes plant cell wall-degrading enzymes on a plasmid. Given the vital role *Stammera* plays in upgrading host digestion of plant material, we investigated the microbe's population dynamics in relation to folivory and stage-specific nutritional requirements. Folivory was quantified as a proxy to assess the beetle's dietary need and growth across developmental stages. Our findings reveal that foliage

consumption is correlated with shifts in host development, increasing significantly over time. Strikingly, *Stammera* abundance remained stable within the foregut symbiotic organs throughout development, despite a rapid increase in its host's overall weight and size as larvae progressed to adulthood. However, the plasmid copy number, and the expression of *Stammera*-encoded plant cell wall-degrading enzymes, were dynamically regulated to meet the dietary needs of a host contending with greater amounts of leaf material. Collectively, our findings demonstrate that transcriptional plasticity, rather than *Stammera* population size, mediates symbiont contributions to host physiology. Our findings highlight how symbiosis supports stage-specific nutritional and physiological needs, providing insights into the molecular and evolutionary dynamics of host-symbiont interactions, co-evolution, and adaptation.

Breaking eco-evolutionary feedbacks leads to extinction in a bacterial mutualism

Baranovitch Y¹

¹The Hebrew University of Jerusalem

POSTER SESSION 2 - **P02.142**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Coevolution is a key force structuring how ecological communities form and function. Specifically, eco-evolutionary feedbacks (EEFs), consisting of reciprocal adaptations between interacting species, are thought to be a key mechanism driving coevolution within communities. EEFs have been shown to be crucial in antagonistic interactions, where they lead to evolutionary arms races. However, the effect of EEFs on other types of interactions is poorly understood. In particular, it is unclear whether EEFs reinforce or degrade mutualistic interactions, which are widespread interactions shaping ecological communities. To address this knowledge gap I developed an experimental system that allows evolving one species in the presence

of another species that is maintained in its ancestral state, preventing any EEFs. Using this system, I (co)evolved a pair of *Escherichia coli* strains that exchange essential amino acids and form an obligate mutualism. Surprisingly, preventing EEFs destabilized our system, and both species survived only when they coevolved. The survival was driven by the evolution of one of the species that evolved to higher density, reducing its amino acid requirements for growth and thereby supporting its partner's survival. These findings reveal a case in which the evolution of one species plays a key role in preventing the extinction of its partner, underscoring the intricate dynamics of coevolution within microbial communities.

Characterization of *Klebsiella pneumoniae*-Targeting Phages in an In Vitro FUT2-Dependent Mucosal Model: Implications for Host-Phage Evolution

Ewertz A¹, Franz C¹, Cho G¹, Hille F¹

¹May Rubner Institute

POSTER SESSION 2 - **P02.145**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: The human FUT2 gene encodes an α 1,2-fucosyltransferase responsible for attaching fucose to glycan chains on mucosal surfaces, thus determining the glycosylation profile of mucus (1). This modification shapes the intestinal microbiome by influencing composition and localization of various microbes, including the opportunistic pathogen *Klebsiella pneumoniae* (Kp) (2). Individuals with a functional FUT2 allele are considered “secretors,” while those homozygous for loss-of-function mutations are classified as “non-secretors”, comprising approximately 20% of individuals in European populations (1). Bacteriophages, which specifically infect and lyse bacteria, may also interact with host mucus glycans in order to enhance retention and antibacterial activity, as proposed by the Bacteriophage adherence to mucus (BAM) model (3). Considering the impact of FUT2 genotype on terminal glycoprotein fucosylation, it may represent a critical host genetic factor to be considered in personalized microbiome-based phage therapies.

Materials and methods: A panel of lytic phages targeting *Klebsiella pneumoniae* strains was characterized through genetic analysis using bioinformatic tools. Host range was assessed in both solid and liquid media. Phage-mucin interactions were evaluated using adhesion and efficiency assays. Mucin preparations included untreated mucin containing terminal fucosylated glycans (representing FUT2 secretor-type mucin) and mucin pretreated with α 1-2-fucosidase to remove terminal fucose residues (representing FUT2 non-secretor-type mucin). In order to specifically investigate the role of fucose in phage-mucin interactions, a competitive binding assay was performed by pre-incubating phages with L-fucose prior to testing in the presence of mucin.

Results: Comparative genome analysis of Kp-specific phages revealed considerable variation in genome size and coding capacity. Host range testing revealed differential lytic profiles across

environmental and antibiotic-resistant, clinical Kp strains. Two phages, classified into the Straboviridae family, harboured a gene homologous to the highly immunogenic outer capsid (Hoc) protein coding sequence, which has previously been associated with mucin glycan binding in T4-like phages (3). Both the predicted protein structure and the immediate genetic context of the Hoc-like gene are similar to those of T4-like phages. Preliminary observations indicate that mucus may enhance phage adhesion on mucins and phage lytic activity against Kp strains. Ongoing assays aim to determine whether terminal fucosylated glycans, shaped by FUT2-dependent mucosal fucosylation, are a critical factor mediating phage-mucus interactions and enhancing lytic efficacy.

Conclusion: Certain phages, especially T4-similar ones, encode Hoc-like proteins that may facilitate interactions with host intestinal mucus. Ongoing work will assess the role of terminal fucosylated glycans, dependent on the host's FUT2 gene status, in influencing phage localization and lytic efficiency. These findings aim to highlight the importance of considering host genetics and host-phage co-evolution in the development of personalized microbiome-modulating therapeutic strategies against opportunistic pathogens like Kp.

Composition of gut microbiota is mostly driven by developmental stage and substrate in an invasive insect pest

Dunis S¹, Rode N¹, Facon B¹, Neuvéglise C², Lapègue M¹, Deschamps C¹, Cesari L¹

¹UMR CBGP, INRAE, ²UMR SPO, INRAE

POSTER SESSION 2 - P02.148, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Over the last decade, many studies have demonstrated that the gut microbiota strongly affects essential traits associated with fitness, such as immunity or growth. For example, axenic *Drosophila* larvae (without any microbiota) cannot develop and die at an early developmental stage. Studies has also shown that the gut microbial community is shaped by the host. However, the relative role of the host life stage, fruit substrate, and host genotype on the composition of the bacterial and fungal gut communities has been less studied.

Here we study how these three factors affect the bacterial and yeast communities composition of *Drosophila suzukii*, an exotic invasive fruit pest that infests multiple host plants.

To test for the potential effects of the host life stage, fruit substrate and host genotype on the gut bacterial and yeast communities of *D. suzukii*, we used a metabarcoding approach by sequencing 16S and ITS

markers. We artificially infested fresh fruits (strawberry, cherry and blackberry) with lab-reared flies (two different genotypes). We extracted larvae from host fruits and transfer them to a pasteurized medium until they pupate. We sampled individuals at each developmental stages (larva, pupa, adult) and fruits before and after infestation.

Our first results indicate that the yeast community is strongly structured among life stages (i.e. larvae, pupae, adults) and among fruit varieties (i.e. strawberry, cherry, blackberry), but not among host genotypes. On the contrary, the bacterial community is shaped mostly by life stages. These preliminary results indicate that metamorphosis plays a crucial role in shaping the gut microbial community. We will discuss how different transmission patterns between bacteria and yeast communities may affect the fitness of insect hosts.

Contextualizing symbiosis: microbial interactions, host environments, and the dynamics of association

Vasse M^{1,2}, Velicer G², Pradeu T¹

¹CNRS, ²ETH

POSTER SESSION 2 - **P02.136**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Symbioses are typically defined as persistent interactions between species, yet the ecological and evolutionary dynamics underpinning these associations are far from fixed. Mounting evidence indicates that the outcomes of microbial interactions—both among microbes and with their hosts—vary widely in their context-dependency. In this talk, I explore the variability in microbial interaction outcomes and how it influences the stability, adaptability, and evolutionary potential of symbioses.

Drawing on empirical work on microbial predation (Vasse et al., 2024, PLOS Biology), I show that even interactions as seemingly directional as predation can reverse under certain ecological conditions, challenging assumptions of fixed roles within microbial communities. In a study of the human vaginal microbiota, we found that the metabolic activity of individual strains is strongly modulated by the presence of other strains or species. These findings underscore that microbial functionality—and, by extension,

effects on the host—cannot necessarily be predicted from isolated taxa alone.

Building on these findings, I discuss a conceptual framework that incorporates a spectrum of ecological context-dependency within symbiosis. This framework considers how host traits—such as immune filtering, niche provisioning, or spatial structuring—can influence whether microbial communities experience more stable or more variable environments, with implications for predictability and evolutionary outcomes.

This work aims to enrich our understanding of symbiosis as a dynamic process mediated by fluctuating ecological conditions and multi-scale interactions. I argue that incorporating interaction variability into our models of symbiosis can better capture the diversity of host-microbe systems and help explain how microbial symbioses function as both stabilizing forces and engines of evolutionary innovation.

Disentangling Ecological Variability: The Role of Richness and Environment in Gut Microbiota Dynamics

Ramirez-Montoya M¹, Fant L², B. Xavier K¹

¹Gulbenkian Institute for Molecular Medicine (GIMM), ²National Institute of Oceanography and Applied Geophysics (OGS)

POSTER SESSION 2 - P02.153, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Understanding the drivers of ecological community variability remains one of ecology's fundamental challenges. Communities in seemingly similar environments often display diverse compositions, yet alike communities can sometimes be found in highly dissimilar environments, patterns that defy straightforward predictions. This unpredictability appears to increase with community complexity, suggesting that ecological interactions play a crucial role in shaping community assemblages. The interplay between biotic and abiotic factors further complicates our understanding of system dynamics, raising important questions about the nature of cross-system variability. In this context, the integration of theoretical frameworks with empirical findings has been crucial to shed light on these intricate scenarios, a strategy that has been adopted in our work.

In this study, we investigate *in vivo* gut microbiota compositions, using two distinct mouse models exposed to varying environmental conditions, to determine to what extent community dynamics follow deterministic patterns. The first mouse model features a conventional microbiota of specific-pathogen-free (SPF) laboratory mice, characterized by high richness and diversity, while the second system consists of a gnotobiotic mouse model colonized with a defined synthetic community of 12 bacterial species, known as the Oligo-Mouse-

Microbiota-12 (OMM12)*. To experimentally manipulate the environment of SPF and OMM12-colonized mice, considering the impact of nutrient availability on the gut microbiome, mice were treated with different diets. By focusing on reproducibility and the relationship between species' average abundance and variability, our research specifically examines how species richness and environmental conditions influence these dynamics.

By analyzing patterns across varying levels of community complexity and diets, we demonstrate that variability is strongly affected by species richness. Fluctuations, which are mostly proportional to abundance when many species coexist (Taylor's law), become sublinear with respect to abundances at low richnesses. Furthermore, to mechanistically understand these systems, we analyze fluctuations in the functional potential of communities to respond to perturbations caused by different dietary treatments, attempting to unravel a possible hierarchy between taxonomic and functional compositions of bacterial communities. We expect that integrating ecological theory with our experimental results will not only characterize the differential ecological principles governing each community but also reveal the biological implications of microbiota functions in response to different diets and their effects on the host.

Eco-evolutionary dynamics of Pisum-Bacteria interactions mediated by reciprocal selection

Angot V¹, Bouchenak-khelladi Y¹

¹UMR Agroécologie, Université Bourgogne Europe, INRAE, Institut Agro Dijon

POSTER SESSION 2 - **P02.125**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Plant-microbiota interactions play a key role in plant adaptation by improving plant nutrient acquisition, abiotic and biotic stress resilience, and overall fitness. While these interactions are receiving growing attention in agriculture and conservation efforts, the ecological and evolutionary processes governing the assembly and function of plant-associated microbial communities are poorly understood. Emerging evidence indicates that these associations may be shaped by co-evolutionary processes whereby host evolutionary history explain its microbiota composition and function. However, these evidences remain limited with much of the recent work focusing on phylosymbiosis. While phylosymbiosis can reflect the influence of host phylogeny on the ecological structure of associated microbiota, it is essential to determine whether it also shapes the phylogenetic structure of the host-associated microbial community and whether closely related hosts associate with closely related microorganisms. Such co-phylogenetic patterns would inform to which extend the plant-microbiota interactions have driven the diversification and adaptation of both partners. We conducted a greenhouse experiment with 24 *Pisum* spp. accessions, comprising a total of 240 individual plants, to study plant-bacteria interactions across different plant-associated microhabitats. Bacterial DNA was extracted from bulk soil, rhizosphere, rhizoplane, endosphere and nodules microhabitats, resulting in the characterization of over 800 bacterial communities with full-length 16SrRNA gene sequencing. Through an integrative framework combining plant and bacterial

phylogenetics, bacterial community ecology, bacterial functional traits and plant growth kinetics, we tested whether these interactions may reflect pairwise coevolution. We show that bacterial communities significantly differ across *Pisum* genotypes and reflect phylosymbiosis, with closely related hosts hosting more similar communities. Furthermore, phylogenetic structure of bacterial communities across host genotypes and plant-associated microhabitats reveals significant clustering, suggesting that plant-bacteria associations selectively favour specific bacterial lineages. Shifts in bacterial community composition and phylogenetic structure were coupled with changes in bacterial functional gene expressions, especially in nitrogen cycling, highlighting that host-driven filtering of microbial taxa may modulate ecosystem functions. Given that host phylogeny best explained the variation in plant developmental rate, we evaluate the degree to which this plant-specific trait relates to the structure and function of bacterial communities. Altogether, these findings suggest that both the host plants and their associated microbial communities act as niche constructors, with reciprocal effects on each other's fitness as reflected in the evolutionary patterns of their interactions. This study significantly enhances our understanding of plant-bacteria interactions by integrating ecological, evolutionary and functional perspectives, and opens new avenues for investigating their coevolution with potential implications for plant adaptation and microbiome-based innovations.

Eco-evolutionary feedbacks in *C. elegans*-microbe interactions link community dynamics to genetic evolution and back

Blankers T¹, Bisschop K²

¹University Of Amsterdam, ² KU Leuven Kulak

POSTER SESSION 2 - **P02.146**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Ecological and evolutionary trajectories of animals and their symbiotic microbes are co-dependent and their interaction is a rich source of adaptive potential. This is illustrated by widespread patterns of phyllosymbiosis and evidence for host-microbe co-speciation as a major predictor for global and local patterns of species diversity. In a series of experiments using the model nematode *Caenorhabditis elegans* and naturally co-occurring microbes, we explored: 1) how host genetics and host behavior shape microbiome assembly; 2) how microbiomes can contribute to evolutionary dynamics in the nematodes; and 3) how nematode evolution feeds back on the assembly of symbiont microbial communities. Nematodes live in bacteria-rich environments and engage with bacteria in a broad range of ecological interactions. Studying nematode-bacteria interactions is fundamentally important for understanding nematode ecology and evolution and the evolutionary ecology of species interactions more generally. In a first experiment, *C. elegans* evolved for 20 generations in the presence of a novel dietary bacterium. The experiment was conducted at five different research institute across the Netherlands and Belgium. Lab-specific environmental bacteria that were sequenced along with the worms were found to influence fitness evolution and the repeatability of evolutionary change. Looking at changes in the *C. elegans* genomes during experimental evolution, we identified candidate genes underpinning adaptive evolution in the microbially diverse environments. Microbial

assembly experiments with knock-out lines for these candidate genes confirmed that these genes functionally affect community assembly in the nematodes. In a second experiment, *C. elegans* evolved for 12 generations under high versus normal salt conditions with and without a gut microbiome. We found that evolving with a gut microbiome facilitated an early evolutionary response to high salt. Evolving in the presence of high salinity modified the gut microbiome assembly of the nematodes. Intriguingly, we found the relative abundance of bacteria known to be involved in salt stress responses in plant root systems to be higher in the nematodes evolving in high salt environments compared to those evolving in unmodified environments. While this can be explained in part by higher fitness of salt tolerant bacteria in saline environments, we also hypothesize that behavior of the nematodes may play a role. In a series of choice experiments we reveal that environmental context drives bacterial preferences in the nematodes, lending support to the host behavior-dependent assembly hypothesis. Together, these results illustrate the intricate relationship between host ecology and evolution and symbiont community composition. By combining Evolve and Resequencing approaches with microbiome assembly experiments in knock-out lines, we begin to uncover genetic mechanisms mediating ecological interactions that feedback onto evolutionary dynamics of host and microbes.

Evolution of gut microbiome during ageing in short-lived African turquoise killifish

Isildak U¹, Ryabova A¹, Guderer I¹, Valenzano D^{1,2}, Donertas H¹

¹Leibniz Institute On Aging – Fritz Lipmann Institute (fli), ²Friedrich Schiller University

POSTER SESSION 2 - P02.143, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Commensal microbes play key roles in multicellular host development, survival, and disease susceptibility. Throughout an organism's lifespan, the composition and metabolic function of microbial communities within the gut undergo substantial shifts, influencing critical phenotypic traits such as nutrient absorption, vitamin synthesis, and protection against pathogens. Despite accumulating evidence of the dynamic evolution of the microbiome within the host, a comprehensive understanding of the ecological and evolutionary processes shaping microbial dynamics over the host's lifespan remains limited.

In this study, we aim to investigate the temporal patterns and mechanisms driving

age-related alterations in gut microbial communities, as well as their potential impacts on host health across different life stages. Leveraging the naturally short lifespan of the African turquoise killifish (*Nothobranchius furzeri*) as a model organism, which possesses a diverse gut microbiota, we aim to characterise the compositional and functional shifts in gut microbiome throughout the ageing process. Our research will explore the interplay between host ageing and microbial dynamics. Ultimately, this work seeks to provide novel insights into the ecological and evolutionary dynamics of host–microbe interactions during ageing, with potential implications for microbiome-based strategies to promote healthy ageing.

Expanding the *P. bursaria*-algal model for endosymbiosis

Malumphy Montesdeoca D¹, Hansson E, Vitonyte I, Cameron D, Brockhurst M

¹University Of Manchester

POSTER SESSION 2 - **P02.133**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The living of one organism within another, endosymbiosis, has evolved independently multiple times across the tree of life and often includes interactions between vastly unrelated organisms. This phenomenon is central to our understanding of the evolution of emergent complexity in modern life and forms a cornerstone in our understanding of ecology, sustainable agriculture and, increasingly, medicine. In natural settings endosymbioses typically occur in the context of complex and diverse ecosystems, however, when studied they are often reduced to one-on-one interactions between two organisms. This reductionist approach risks obscuring important dynamics and evolutionary pressures that emerge in diverse communities. For further mechanistic and evolutionary understanding of endosymbiosis, model systems that incorporate ecological complexity are needed.

Paramecium bursaria has emerged as a model for the study of primary and secondary endosymbiosis in eukaryotes. It engages in a facultative symbiosis with several species of green algae which are housed in specialised vacuoles that mediate the transfer of amino acids and carbon dioxide to the symbiont in exchange for oxygen and photosynthetic products. The host can exert strict control over its symbiont load, optimising it for carbon output per unit nitrogen cost. *P. bursaria* can hold multiple algal species simultaneously, a feature that is yet to be explored experimentally. We propose expanding the *P. bursaria*-algae model to include the study of these naturally occurring tri-partite systems whereby *P. bursaria* plays host simultaneously to microalgae from the genera *Chlorella* or *Micractinium* and picoalgae in the genus *Choricystis* in what we described as dual-algal systems.

To develop this model we tested the viability of 15 different *Choricystis* strains, isolated from free-living and symbiotic populations, to act as symbionts for *P. bursaria* (186b). These strains were tested in cured hosts either as the sole symbiont or in combinations with the host's native symbiont *M. conductrix*. Populations were monitored via flowcytometry, manual counts and fluorescence microscopy. Though all strains were ingested by the host and held in digestive vacuoles, their ability to incorporate and persist in the host's cortex as symbionts varied greatly. Two symbiotic strains (s171 and s160) were capable of sustaining hosts for 6 weeks as the sole symbiont. However, in combination with *M. conductrix*, the native symbiont came to fixation in the long term in most instances. Despite this, many strains of *Choricystis* can cohabit the host's cortex for up to two weeks, while others showed signs of longer-term stability (further investigation is needed for confirmation). These data suggest a window of opportunity for short- and medium-term experimentation to take place.

These findings allow for a more ecologically relevant model system in which questions of host control, symbiont compatibility, and evolutionary trajectories can be examined in a tripartite system. Our next line of investigation is to test the fitness outcomes of hosts infected with *Choricystis* alone, *M. conductrix* alone and a combination of the two along a light gradient to determine host control over the novel symbiont load, and fitness outcomes for all involved. This allows us to gain novel insights into how novel symbioses can be formed and stabilised in diverse ecosystems. By increasing the number of selfish entities that simultaneously co-habit the host, we hope complexity seen in nature can be mirrored in a tractable system.

Experimental evolution within the bee gut

Ganesan R¹, Kwong W¹

¹Gulbenkian Institute For Molecular Medicine

POSTER SESSION 2 - **P02.139**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Many animals have successfully expanded into a range of ecological niches in part due to the benefits conferred by their microbial symbionts. These beneficial symbionts may provide essential nutrients, defence against antagonists, or protection from abiotic stressors. While studies have explored the functional benefits of host – microbial symbioses, how symbionts establish themselves in a novel host and the how partner – specificity evolves is less known. From the microbial perspective, we hypothesize that differences in strain origins, growth conditions and interactions with other community members influence their evolution and establishment within the host. Experiments with a tractable symbiotic system where we can perform host – switching and experimental evolution in vivo will help us observe the genomic changes that occur during host – specialisation and understand the factors that influence within – host symbiont evolution. For this, social bees and their well-defined set of beneficial gut microorganisms comprising mainly of *Snodgrassella*, *Gilliamella*, *Lactobacillus*, *Bombilactobacillus*, *Bifidobacterium*, are a simplified and experimentally tractable model system. Bee gut microorganisms help in breaking down complex plant substrates to provide nutrients and also provide colonisation resistance. Although the core microbial species associated with the host are consistent across eusocial corbiculate bees, studies show that, at the strain level,

the symbionts exhibit high diversity and host – specialisation. Eg. Strains of *Snodgrassella* isolated from bumble bees, do not effectively colonise honey bees and vice versa. What led to strain specialisation in the bees and can a non – native strain adapt to the bee gut through frequent exposure? To study this, native honey bee gut microbial strains (*Snodgrassella alvi* KFP26 and wkB2) and a non – native bumblebee gut microbial strain (*Snodgrassella communis* wkB12) were introduced to honey bees. Monocultures of the strains were fed to honey bees in a cup cage. Five days post-inoculation, gut contents of the colonised bees were fed to a new group of newly emerged bees. At the end of each passage, the CFU counts of each strain in the honey bee guts were estimated. After six passages, we enrich for bacterial cells from individual bee guts and extract bacterial DNA for shotgun metagenome sequencing to identify variants in the evolved population. We observe that the native and non-native strains always colonise ~100% and ~50% of the bees in each passage. In the evolved strains, we aim to pinpoint microbial genes or loci that are under selection and understand how it affects strain adaptation in vivo. Ultimately, through within – host evolution experiments in the presence of the rest of the gut microbial community we wish to enhance our understanding of microbial evolution and factors that lead to host – specialisation in bee gut bacteria.

Exploring the evolutionary ecology of microbes associated with the common garden snail

Matthews A¹

¹University Of Exeter

POSTER SESSION 2 - **P02.147**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The common garden snail *Cornu aspersum* is a cosmopolitan agricultural pest. A snail's body wall presents to its environment a mucosa rich in specialised glandular cells, which are believed to perform essential nutritional and defensive functions. Though overlooked, this mucosa plays a central role mediating microbial interactions. Here we explore *C. aspersum*'s cuticular microbiome.

Snails sampled across Europe were characterised by nanopore 16S rRNA sequencing mucus, revealing a microbiota rich in *Erwinia* sp. and *Pseudomonas* sp. Confocal fluorescent microscopy confirmed that bacterial symbionts are resident in cuticular bacteriocytes, and especially abundant in the anterior portion of the foot

and in the mantle. Symbionts could be cured using high doses of antibiotics, but this was associated with high snail mortality. Provision of antibiotic-resistant *Pseudomonas* symbionts rescued hosts from death, however the extent of colonisation was negatively correlated with host growth in surviving individuals. Using RFP-transformed antibiotic-resistant *Pseudomonas* to visualize invasion, we observed competitive exclusion by resident strains even under strong antibiotic selection favouring the invader.

Our results suggest that symbiosis in *Cornu aspersum* is widespread, primarily based on diverse strains of *Pseudomonas*, and that one of its likely functions is mucosal immunity.

Foregut microbial communities and the possibility of endogenous ethanol production in honeybees

AntoŹ W¹, Ostap-Chęć M¹, Surmacz B¹, Stec D¹, Miler K¹

¹Institute of Systematics and Evolution of Animals, Polish Academy of Sciences

POSTER SESSION 2 - **P02.128**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Honeybees encounter low doses of ethanol in the environment, primarily in fermenting nectar, which can have both negative and positive impact on their physiology. However, we recently detected traces of ethanol in the crop (part of the foregut) contents of caged bees maintained without access to environmental food sources, raising the possibility of endogenous ethanol production mediated by the microbiota. While the honeybee gut microbiota is known to be composed of a small number of 'core' species typically concentrated in the hindgut, the crop is considered particularly poor in bacteria. At the same time, the primary function of the crop is to store and transport the ingested food. We hypothesized that shifts in the crop microbiota under laboratory conditions may facilitate fermentation, potentially contributing to endogenous ethanol accumulation independent of environmental exposure.

Materials and methods: We analyzed ethanol levels in crop contents (n = 207, 3 µl per sample) from two groups of the same age: caged bees fed sucrose solution and naturally foraging hive bees. Ethanol concentrations were quantified using a spectrophotometric assay. To characterize microbial communities, pooled crop contents were subjected to 16S rRNA (V3-V4 region) metabarcoding, resulting in 11 and 12 group-level samples. Amplicon sequence variants (ASVs) were assigned to taxonomic units using the BEEexact database, specific to the bee microbiome. Microbial communities were compared using α- and β-diversity metrics, DESeq2 differential abundance testing, constrained correspondence analysis (CCA), and comparisons of within-group divergence and generalized linear mixed models (glmmTMB) focusing on key genera.

Results: Mean ethanol concentrations in both groups were low and near the method's detection threshold (~0.012 g/l in hive bees,

~0.007 g/l in caged bees), but non-zero measurements were more frequent in caged bees. Microbial community structure differed strongly between groups: caged bees hosted significantly fewer ASVs (981 vs. 2,358 in hive bees), with only 7% of variants shared. At the genus level, diversity was also reduced, but β-diversity was higher among caged bees, indicating greater within-group divergence. In caged bees, the abundance of genera connected with flower nectar (like *Apilactobacillus*), which constituted the majority of hive bees' crop microbiota, was significantly decreased. Several genera were enriched in caged bees, three of which represent the bees' core microbiota, including *Gilliamella*, capable of producing ethanol. This indicated the potential to acquire ethanol not only from the environment but also from metabolic processes performed by bees' microbiome.

Conclusions: Our findings suggest that under constrained dietary and environmental conditions, crop-associated microbial communities may acquire novel, or enhance existing, metabolic functions, including the ability to ferment sugars into ethanol. These changes include a loss of microbial diversity and a shift in community composition, at least in part toward fermentation-capable taxa. Our study highlights the dynamic nature of host-microbe interactions in honeybees and raises the possibility that the bee microbiota contributes to modulation of endogenous ethanol levels, with potential consequences for host physiology and behavior. The extent of these consequences remains to be studied, but our results already underscore the evolutionary and ecological significance of microbial symbioses as sources of phenotypic plasticity in host species.

This research was funded by the National Science Center in Poland, Sonata 17 grant 2021/43/D/NZ8/01044.

Host-gut microbiota coevolution in insular populations: A case study of the Balearic lizard *Podarcis lilfordi*

²Institute for Research on Biodiversity (IRBio), ³Animal Demography and Ecology Unit, IMEDEA, Consejo Superior de Investigaciones Científicas

POSTER SESSION 2 - P02.132, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Insular populations, due to their isolation, provide a great natural system to explore evolutionary processes between vertebrates and their gut microbes. Through population-level studies, they allow us to investigate critical questions such as how host genetics affect gut microbial community structure.

To address this, we studied multiple populations of the endemic Balearic lizard *Podarcis lilfordi*. Using full-length 16S rRNA sequences (Oxford Nanopore Technology) from fecal samples of 240 individuals across 11 islets, we generated gut microbial profiles and coupled them with host population genetic distances based on the fixation index (FST) and single-nucleotide polymorphisms (SNPs). To minimize the influence of extrinsic factors in shaping gut microbiota composition, we focused only on bacterial taxa present in at

least 80% of individuals within each population (i.e., the core 80%).

All populations showed a remarkably conserved core gut microbiota taxonomic profile, despite having been isolated for 4,000–9,000 years, suggesting ancestral inheritance and a strong resilience of these bacterial communities. Relative distances among populations inferred from gut microbiota closely mirrored those based on host population genetics, pointing to an influence of the host phylogeographic history on gut microbial composition. Additionally, we identified a set of bacterial genera responsible for this pattern, which likely represent the “housekeeping” component of the lizard gut microbiota. These taxa emerge as important candidates for future studies aimed at better understanding host-microbe coevolution and its role in insular adaptation.

Investigating Past Human Mobility and Interactions in the Southern Cone of the Americas using Phylogenomics of Ancient Commensal Microbes.

POSTER SESSION 2 - P02.120, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Dental calculus, the calcified biofilm that accumulates on teeth's surfaces during an individual's life, preserves an exceptional archaeogenetic record of hundreds of microbial species that are part of the human oral microbiome. However, most of what we know about oral microbiomes is based on modern samples, and little is known about how these human-microbe associations were established over large spatiotemporal scales. Previous metagenomics works –on modern and ancient samples– have found relatively low differences in the oral microbiome composition of populations from different periods and continents. Thus, we hypothesised that if oral microbial species are maintained within human populations over long periods, their genomes could reflect human population movements through time. To test this hypothesis, we sequenced and analysed ancient dental calculus samples from multiple individuals from

the Southern Cone of the Americas, a region with a rich archaeological record, but underexplored using paleogenomic approaches. Phylogenomic methods were used to reconstruct the relationship between strains of oral microbial species recovered from individuals across multiple spatiotemporal contexts. When combined with archaeological data, we revealed several species with strong spatiotemporal associations with their host populations. Together, our results bring not only unprecedented information about the oral microbial diversity associated with indigenous populations of South America but also novel insight into the long-term association between humans and their commensal microbes. We propose that this type of data and the implemented analytical approaches could be also used as a novel and complementary approach to investigate the mobility and interactions of ancient human populations.

Investigating signatures of local adaptation in the ubiquitous forest ectomycorrhizal fungus *Cenococcum geophilum*

Zimmermann F¹, Dauphin B¹, Peter M¹, Croll D², Tarkka M³, Opgenoorth L⁴

¹Swiss Federal Research Institute for Forest, Snow And Landscape Research WSL, ²University of Neuchâtel, ³Helmholtz Centre for Environmental Research, ⁴Philipps University Marburg

POSTER SESSION 2 - P02.123, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: Rising temperature- and drought-induced stress on European forests has increased tree mortality, yet little is known about the genetic mechanisms of climate adaptation in their associated ectomycorrhizal fungi and the role of a common evolutionary history. We focus on the symbiotic interaction of Pedunculate oak (*Quercus robur*), a ecologically and economically important forest tree species, and *Cenococcum geophilum*, a widespread, drought-resistant ectomycorrhizal fungus with a broad host range, often dominant in temperate and boreal forest ecosystems.

Materials/Methods: Using in situ soil measurements and modeled atmospheric data across 21 sites within the range of the host tree, *Quercus robur*, we isolated fungal strains from three soil depths per site. We will conduct whole genome sequencing of individual strains to identify genotype-environment associations and pinpoint genomic regions underlying local adaptation, especially selective pressures associated to biotic and abiotic factors. Additionally, we will genotype 16 oaks per site to investigate population structure and the shared demographic history of this host-fungus pair. Finally, we will identify genotype-genotype co-occurrences in host and symbiotic partner that are associated with certain environmental conditions.

Results: We expect to find various *C. geophilum* lineages within and across sampling sites and depths, with specific gene variants to be associated with soil chemistry and water availability. In addition, we anticipate complex gene pathways involved in adaptation to local dry conditions with functions related to melanin production and other desiccation-resistance traits. We expect *Q. robur* populations to be mainly structured along a latitudinal gradient, by topography, and other persistent barriers. Also, we expect to find varying admixture levels of individuals within and between populations. Finally, we expect to identify genotype-genotype combinations that are associated with certain climatic and soil conditions and to identify coincidences of effective population sizes (N_e) of *Q. robur* and its dominant symbiotic partner *C. geophilum*.

Conclusion: Identifying common selective pressures acting on both, tree and fungal populations will help clarify co-adaptation processes, despite the challenge of detecting signals of local adaptation due to symbiotic interactions. Understanding the impact of extreme climatic events on both partners of a symbiotic mycorrhizal relationship is essential for assessing processes of environmental adaptation and the underlying gene variants involved in natural selection.

Is bird egg sterile? Challenges of metabarcoding in a low-biomass microbiome study

POSTER SESSION 2 - P02.149, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

How and when the first bacteria colonise the gastrointestinal tract (GIT) in vertebrates remains a key, yet difficult-to-test question in evolutionary biology. Several influential studies over the last decade have suggested that bacterial colonisation may begin during early embryonic development. While recent mammalian studies challenge the idea of in utero colonisation—pointing instead to birth as the starting point—the timing and mechanisms of gut colonisation in birds remain elusive, largely due to inadequate methodology for microbiota profiling of low-biomass samples, which results in contamination and other artefacts not being filtered out and incorrectly considered as symbiotic microbiota.

Are bird eggs initially sterile, or do females seed them with bacteria to influence early microbiome development? This is an important question, as early bacterial colonisers may shape the GIT and the immune system development, affecting survival and microbiome communities after hatching. Bird eggs are well protected by various mechanical and chemical barriers, including a cocktail of antimicrobial peptides, yet some pathogens (such as *Salmonella*) can still overcome the defences. Three mutually non-exclusive hypotheses can explain avian GIT microbiota recruitment: (1) Eggs are sterile at laying (Sterile egg hypothesis) and (2) colonizations occur after oviposition by horizontal trans-shell migration, and/ or (3) vertical transmission occurs from the maternal oviduct.

To elucidate the mechanisms contributing to the formation of the gut microbiota in avian embryo, we examined the microbial communities in freshly laid eggs (day 0; E0), developing embryos (E13) and the digestive tract of a wild passerine, the great tit (*Parus major*) in our recent study (Tesicky et al. FEMS Microb.Ecol. 2024). Employing a methodologically advanced approach combining 16S rRNA gene

metabarcoding and microbe-specific qPCRs, our protocol allowed us to reliably distinguish symbiotic bacteria from environmental contaminating and cross-contaminating bacteria.

Bacterial profiles in eggs and embryos were dominated by environmental contaminants. After filtering these out, we revealed that the avian egg is nearly sterile but acquires a slightly richer microbiome during embryonic development. Of the three potentially pathogenic bacteria targeted by the more sensitive qPCR, only *Dietzia*, was found in the E0 eggs (yet also in negative controls), in the E13 guts and in the female samples, which could indicate possible vertical transmission.

These findings demonstrate that in passerines the initial gut microbiota is dominantly established after hatching, aligning with dynamic microbiome shifts observed in nestlings. They also align with recent publications highlighting methodological shortcomings, particularly insufficient contamination control in previous studies as environmental contamination and cross-contamination are common yet often overlooked issues in many studies based on amplicon sequencing, especially those using low-biomass DNA samples. We will also discuss methodological strategies to minimise these issues. While broader taxonomic sampling is still needed, our findings suggest that despite 310 million years of divergence, birds and mammals may share similar microbiota colonisation strategies.

Understanding the mechanisms of early GIT microbiota establishment can shed light on parental effects in birds and contribute to basic knowledge of host-microbe evolutionary ecology as well as zoohygienic and veterinary measures that minimise the risk of disease transmission.

Micromanaging: The architecture and evolution of host control in a microbial symbiosis

Hansson E¹, Savory F², Milner D², Malumphy Montesdeoca D¹, Vitonyte I¹, Deadman N¹, Kilias E², Richards T², Cameron D¹, Brockhurst M¹

¹University Of Manchester, ²University of Oxford

POSTER SESSION 2 - P02.130, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Endosymbiosis is foundational to the origin of complex life and plays a central role in both natural and manmade ecosystems. By enabling functional compartmentalisation and evolutionary innovation, symbiosis underpins ecological processes and services at multiple levels. However, the molecular mechanisms that govern the evolution and stability of endosymbiotic relationships remain poorly understood, particularly in nascent or facultative symbioses where the fitness optima of host and symbiont may differ considerably. As endosymbiont cells live inside their hosts, the hosts evolve to regulate and control the growth and metabolism of its symbionts, but experimental data testing what happens when disrupting these controls is lacking.

Here, we investigate host control in the ciliate–algae symbiosis between *Paramecium bursaria* and *Microactinium conductrix*, a uniquely tractable model of facultative endosymbiosis. In this system, algal symbionts are individually housed in peri-algal vacuoles, where they exchange photosynthetically derived carbon and oxygen for nitrogen, carbon dioxide, ions, and protection against grazers and viruses. Hosts dynamically regulate their symbiont load in response to environmental conditions, particularly light, balancing the cost of provisioning nitrogen with the benefit of receiving carbon. Previous work has identified two putative host control mechanisms: a “carrot”, in which nitrogen provisioning via the arginine-to-polyamine pathway promotes symbiont growth and sugar release; and a “stick”, in which digestion of symbionts enables the host to reduce algal load, with sensing of breakdown products via the glycan processing pathway signalling successful digestion.

To test how these control pathways contribute to symbiosis stability and host fitness, we chemically disrupted each control mechanism by supplementing specific pathway intermediates and monitored population-level growth of hosts and symbionts using flow cytometry across replicated cultures. Preliminary results show targeting these pathways chemically has the potential to shift the cost:benefit balance, and even disrupt the symbiosis and lead to population extinction. Furthermore, the response depends on the step in the pathway targeted, and in the case of the arginine-to-polyamine pathway, N supplementation outwith the pathway does not show the same effect. We are currently testing how these disruptions interact with light environment, a key ecological axis along which host and symbiont fitness optima diverge. By the time of the conference, we will also have completed fitness assays under light × control mechanism compound combinations, along with untargeted metabolomics to assess the broader phenotypic impact of control disruption.

Although layered control architectures have been identified in other symbioses (including coral–algae and legume–rhizobia systems), the integration of multiple host control mechanisms and their impact on phenotypic plasticity and symbiotic stability have not been experimentally tested. This work will provide novel insight into how host control systems are structured, and how they determine the robustness of symbiosis under environmental variability. These questions are increasingly urgent as climate change places critical symbioses – such as those in coral reefs and agricultural systems – under unprecedented stress.

Mitochondrial adaptation regarding different chloroplast retention capabilities in Sacoglossa

POSTER SESSION 2 - P02.154, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

‘Solar-powered’ sea slugs belong to a small group called Sacoglossa within Heterobranchia and have the ability to sequester chloroplasts from its food algae. These ‘stolen’ plastids (known as kleptoplasts) are then stored in a still functional state in the slugs’ digestive gland cells. During this time the kleptoplasts continue photosynthesis inside the slugs building up a starch reservoir. The chloroplast retention abilities of sacoglossan species varies, and we distinguish between 1) non-function retention forms, in which the chloroplast does not stay active inside the slugs, 2) short-term retention forms, in which the chloroplasts stay active for a few weeks, 3) long-term retention forms, in which the chloroplasts stay active for several months, and 4) some forms, which do not incorporate the chloroplasts at all. Studies on plants

have shown that plastid and mitochondrial functions are interconnected to support essential cellular processes, such as energy production, metabolism and stress responses. However, the potential impact of kleptoplasts on mitochondria in sacoglossan species with varying chloroplast retention capabilities remains unexplored. Our aim is to search for mitochondrial adaptations/mutations in relation to their different chloroplast retention capabilities. We have assembled and annotated the mitochondrial genomes of 40 sacoglossan species representing all the different chloroplast retention forms. Phylogenetic analyses using IQ-TREE confirmed the most recent Sacoglossa phylogeny. We will analyze potential selective pressure on individual mitochondrial genes, using the programs PAML and HyPhy.

Pathogen Discovery in Ancient Cattle Remains: Possible Cause of Taurine Extinction in Thailand

Surat W¹, Sangtubsorn N¹

¹Kasetsart University

POSTER SESSION 2 - P02.118, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Cattle were domesticated in Thailand for thousands years ago and genetic evidence of cattle remains dated 1700-3500 years before present (YBP) indicated that *Bos taurus* or taurine were domesticated in Central and Northeastern Thailand during the prehistoric period. However, nowadays *Bos indicus* or zebu cattle are only traditional cattle in this country. The findings suggested that the extinction of Thai taurine had occurred. In the past, the importation of zebu into Africa caused a massive reduction of taurine (90%) due to an infectious disease but the zebu which had higher resistant to tropical diseases was killed only 30%. Hence, it was possible that the extinction of taurine in Thailand was due to an epidemic of infectious diseases after zebu had imported into the country. In this study, we aimed to identify cattle species and reveal pathogenic agents in the ancient cattle remain in Thailand in the Dvaravati period in which Indian culture had influence in the country.

The cattle remain was identified by DNA and morphology. Next Generation sequencing was performed and then genomic data were used to identify cattle species and classify pathogens. The results showed that the cattle remain belonged to taurine or a hybrid between taurine and zebu. The finding suggested that zebu may have been introduced into Thailand in the Dvaravati period. The total of 26 pathogenic bacterial species and 5 pathogenic viruses causing death in cattle and other mammals were detected. Some of them can kill cattle and humans including *Yersinia* sp. which had killed millions of humans in the past. *Campylobacter* sp. detected in this study can lead to difficult pregnancies and abortion in cattle and humans in present day. The result contributed that the pathogens causing death in cattle detected in this study have circulated in the cattle population since the Dvaravati period and some of them may cause the extinction of taurine in Thailand.

Patterns of correlation between mycorrhizal specificity and host genomics in *Platanthera* orchids across Eastern North America

POSTER SESSION 2 - P02.155, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Orchids, with their obligate dependence on specific mycorrhizal fungi and often narrow ecological niches, provide a powerful system for investigating how microbiome associations influence plant ecology and evolution. All orchids require compatible orchid mycorrhizal fungi (OMF) from their environment to germinate and establish seedlings, making fungal availability a key determinant of their local distribution. Most orchid species associate with a limited range of fungal partners, and it has been hypothesized that specialization to particular fungal lineages may contribute to lineage differentiation and species diversification in orchids.

To explore this, we identified OMF partners in 19 taxa in the terrestrial orchid genus *Platanthera*, from populations across

Eastern North America from Wisconsin and New Hampshire to Florida. We integrated fungal association data with host population genomic analyses to assess (a) whether OMF associations and degree of specialization differs among related orchid species and (b) whether more closely related orchid species have more similar OMF than distantly related orchid species. We found that most orchid species consistently associated with distinct clades of OMF, but that level of specificity varied. Orchid species which are known to form natural hybrids, exhibited broadly overlapping fungal associations. Our data indicate a strong correlation between host genomics and OMF partners. We discuss how host-microbiome interactions may contribute to speciation and diversification in orchids.

Persistence of an Influential Passenger: The Endosymbiotic Association of *Wolbachia* with the Neotropical Fly *Drosophila willistoni*

Martins M¹, Cogni R¹

¹University Of São Paulo

POSTER SESSION 2 - **P02.150**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Background: The endosymbiotic bacterium *Wolbachia* is widespread in arthropods, largely due to its remarkable capacity to manipulate host reproduction and confer fitness-related traits. These traits—such as antiviral protection, altered host behavior, and increased fecundity—are often modulated by environmental factors, especially temperature. Temperature affects *Wolbachia* bacterial densities (titer), maternal transmission efficiency, and the expression of symbiont-conferred phenotypes, making it a key environmental variable in host-symbiont dynamics. While high *Wolbachia* titers are often necessary for beneficial traits like pathogen protection, they may also impose costs to the host. Despite extensive research in model organisms, little is known about how these dynamics play out in non-model Neotropical species, where *Wolbachia* presence and diversity remains underexplored.

In *Drosophila willistoni*, a widely distributed Neotropical species, *Wolbachia* prevalence is variable and driven by factors that are not yet well understood. Previous work suggests the presence of two infection types: one systemic, where *Wolbachia* is present in every host cell; and, one restrict, where *Wolbachia* is present only in neural cells and in the germline. Moreover, unlike other hosts, there is little evidence of *Wolbachia* manipulating reproduction in *D. willistoni*, raising the question of what evolutionary forces sustain these infections. Here we aim to: (1) assess whether *Wolbachia* titer is stably inherited across different temperatures; (2) determine if variations in titer are associated with distinct bacterial strains; and (3) evaluate how titer levels and strain identity correlate with host fitness and antiviral protection. By investigating these aspects, we seek to test known assumptions and enhance our understanding of host-symbiont interactions in diverse ecological contexts.

Materials and Methods: We collected 80 isofemale lines of *D. willistoni* from the Atlantic rainforest. We assessed *Wolbachia* infection using PCR and qPCR in whole females and dissected ovaries. Titer levels were quantified across different rearing temperatures (18°C and 25°C), ages, and tissues. Selected lines were subjected to reciprocal crosses with uninfected counterparts (UN) to evaluate reproductive compatibility. To test for antiviral protection, flies were challenged with *Drosophila C virus* (DCV). Representative high-titer (HT) and low-titer (LT) strains were genome sequenced.

Results: *Wolbachia* was detected in 61.3% of the isofemale lines. Based on titer, we classified 44 lines as high-titer (HT), 4 as low-titer (LT), and 31 as uninfected (UN). Infection prevalence was consistent with previous data from 2019, suggesting stable maintenance. HT strains showed systemic infection across tissues and maintained stable titers across temperatures and fly ages. LT strains were unstable and were lost in the laboratory over the generations. Crosses involving HT and LT lines and *D. paulistorum* revealed partial reproductive isolation and asymmetric maternal transmission. Genomic analysis showed the HT strain closely related to wWil and wAu, while the LT strain resembled wMel. Only the LT strain carried CI-associated genes. Despite high titers and systemic distribution, no antiviral protection against DCV was observed in HT-infected *D. willistoni*.

Conclusions: Our results reveal the coexistence of two divergent *Wolbachia* strains in a single *D. willistoni* population, each with distinct genomic signatures and infection dynamics. The HT strain appears to be stable, while the LT strain likely represents a recent horizontal acquisition. The absence of reproductive manipulation and antiviral protection, in systemically infected flies, suggests that its maintenance may rely on other ecological or evolutionary mechanisms. This study underscores the importance of examining the diversity of strategies used by endosymbionts to persist.

Phylosymbiosis and other factors shaping gastrointestinal microbiota composition of captive parrots: interspecific and intraspecific variation revealed by large-scale profiling

Marková K¹, Schmiedová L^{1,2}, Grymová V³, Tesický M^{1,2,4}, Kreisinger J¹, Vinkler M¹

¹Charles University, Faculty Of Science, Department of Zoology, ²Czech Academy of Science, Institute of Vertebrate Biology, ³Veterinary clinics Avetum, ⁴Ludwig Maximilian University, Faculty of Veterinary Medicine

POSTER SESSION 2 - **P02.134**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Phylosymbiosis, patterns of host-associated microbial community structure driven by evolutionary history of host species, is most often studied in various invertebrates or mammals, but only scarcely in birds. Captive parrots (Psittaciformes) combine the advantages of laboratory models (uniform environmental conditions) and wild animals (high diversity of species available), which makes them convenient models for host-microbiota association studies. Furthermore, domestic parrots are susceptible to numerous health issues that can be linked to gastrointestinal tract microbiota (GM) either directly or via gut-brain axis, highlighting the veterinary relevance of GM-oriented research in this group of hosts. Yet, the parrot GM is highly underexplored. Here, we addressed the interspecific and intraspecific variation in healthy parrot-associated GM, questioned the level of phylosymbiosis and identified the main factors shaping GM composition and diversity. We analysed faecal and oral microbiota of 277 individuals from 66 parrot

species through 16S rRNA gene profiling. Faecal and oral microbiota differed in composition, with oral microbiota having significantly higher alpha-diversity and lower interindividual variation. We did not find any core OTU or bacterial genus that would be present in faecal or oral samples of all individuals or species studied. We revealed high interspecific and intraspecific variation in both faecal and oral microbiota, with host species and owner identity being the most important factors influencing microbial composition and diversity, followed by sex and season. Individuals representing the same parrot species or genus shared similar GM communities, but no clear phylogenetic signal was observed in GM composition among more distantly related host taxa. These results indicate that the parrot-GM reciprocal adaptations lead to phylosymbiosis across closely related lineages, but the signatures of these interactions fade at higher phylogenetic levels.

Plant conservation hologenomics: combining population genomics with microbiont community assessments for two orchid species in Denmark

Hartvig I^{1,2,3}, Bünner M¹, Madsen I¹, Bourbonnais A¹, Aerenlund H, Nielsen L², Gilbert M¹

¹Center for Evolutionary Hologenomics, Globe Institute, University of Copenhagen, ²Dept. Geoscience and Natural Resource Management, University of Copenhagen, ³Smithsonian Environmental Research Center

POSTER SESSION 2 - P02.121, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

As the importance of the microbiome for plant health and ecology becomes increasingly evident, it seems clear that effective conservation of wild plant species needs to integrate knowledge on both the plants and their microbionts, i.e., the holobiont. Conservation of the genetic diversity in a plant species could, therefore, be extended to involve considerations for its diversity of functionally important microbionts. Population genomics offers valuable tools for designing better conservation strategies for vulnerable plant species, but does not take into account host-specific interactions with and dependence on specific microbionts. We propose that integrating population genomics with host microbiome studies into a wider plant conservation hologenomics context is needed for the conservation of the plant holobiont. This approach offers novel levels of understanding habitat requirements,

landscape genomics and identification of evolutionary significant units. With their dependence on specific mycorrhizal fungi (OMF), orchids provide a great illustration of the importance of the microbiome component in conservation studies. While it is known that most orchids have specific requirements for their mycorrhizal partners and that abundance of OMF in the soil effects distribution of the orchids, there is a scarcity of knowledge on how the orchid mycobiome varies with populations and across the landscape, and how it correlates with host genomic variation. We here demonstrate an orchid conservation hologenomics approach by combining population genomics with root mycobiome data for two closely related orchid species (*Platanthera chlorantha* and *P. bifolia*) across populations in Denmark, and discuss the implications of our findings for conservation efforts.

Quantifying the impact of insect host genotype on Wolbachia titer

MATIN M¹, Rode N¹, Gautier M¹, Serga S¹

¹Cbgp Inrae

POSTER SESSION 2 - **P02.141**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Wolbachia are the most abundant endosymbiotic bacteria found in arthropod species, known to induce a wide variety of phenotypes on their hosts, with strong evidence indicating that some fitness-associated host traits depend on bacterial load.

Here we quantify how Wolbachia titer is influenced by the genome of its host, in *Drosophila melanogaster*, using the *Drosophila* Genetic Reference Panel (DGRP).

We first found a large variation in Wolbachia titers among 90 DGRP lines, using read mapping coverage data to estimate titers in silico.

We found high broad-sense heritability for Wolbachia titer variation. To identify the host loci associated with this phenotype, we performed a genome-wide association study using 1,202,368 biallelic SNPs.

Finally, we validated our estimation of Wolbachia titers in silico using direct estimation with qPCR.

We discuss our results in light of previous studies in *D. melanogaster* and *D. simulans*, and we conclude that our research brings further evidence of Wolbachia titer regulation by the host genome, illustrating the complexity of host-endosymbiont relationships.

Ruling the kingdoms: coordinated stress responses in a lichen-forming fungus partnered with algal or cyanobacterial symbionts

Goss A¹, Werth S¹

¹Ludwig Maximilian University of Munich

POSTER SESSION 2 - **P02.129**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Symbiotic associations play a central role in shaping the ecological niches and evolutionary potential of both hosts and their microbial partners. In lichens, photobiont identity can influence habitat range, physiology, and even reproductive strategy. Yet the contributions of each partner to environmental adaptation and specialization remain poorly understood.

The foliose lichen *Sticta canariensis* forms a rare photosymbiodeme composed of two morphotypes: one associating with the cyanobacterium *Nostoc* (cyanomorph), and the other with the green alga *Symbiochloris* (chloromorph). These morphs differ not only in symbiotic composition but also in phenotype and microhabitat preference, offering a valuable example of symbiont-driven ecological diversification.

To investigate the molecular basis of stress response in this complex symbiosis, we examined transcriptional responses to short-term temperature variation across the eukaryotic symbionts of *S. canariensis*. Using RNA-seq and co-expression network analysis, we observed morph- and temperature-specific transcriptional shifts. These included coordinated shifts in stress responses and metabolic processes. The observed coordination of stress responses reflects a key facet of phenotypic plasticity in the lichen symbiosis and may contribute to ecological specialization and long-term adaptability in the face of environmental change.

Social transmission of the microbiome in wild baboons

Debray R¹, Gilbert J², Alberts S³, Archie E⁴, Tung J^{1,3}

¹Max Planck Institute For Evolutionary Anthropology, ²University of California, San Diego, ³Duke University, ⁴University of Notre Dame

POSTER SESSION 2 - P02.119, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Animals form stable associations with microbial communities that aid them in breaking down certain nutrients and in developing their immune systems. However, many gut bacteria have evolved to become so specialized that they can no longer survive outside of their hosts, raising the question of how animals acquire members of their microbiome that they are unlikely to encounter in their environments. One theory is that close social interactions promote microbial transmission, allowing animals to pass around specialized bacteria without losing them, and that selection on microbiome transmission may therefore contribute to the evolution of some forms of social behavior. To test this hypothesis, we integrated strain-resolved metagenomics with detailed behavioral and demographic data from the intensively studied population of wild baboons in the Amboseli ecosystem of Kenya. To characterize the gut microbiome, we collected fecal samples from a population of 132 baboons—all of the adult members of five social groups (n=398 samples). Transmission occurred more often

between members of the same social group than between members of different social groups. Within social groups, transmission was most common among close social partners that frequently engaged in grooming behaviors. Baboons that had recently migrated between social groups were disproportionately involved in transmission events, suggesting that dispersing animals bring new strains or species that their group members may not have encountered. Finally, bacterial species whose transmission patterns followed the social network remained in their hosts for significantly longer durations than bacterial species whose transmission patterns did not correlate with the social network, suggesting that bacteria that rely on social transmission are more likely to be particularly adapted to their hosts. Our results suggest that social behaviors can facilitate microbial transmission, particularly of specialized bacteria, and may provide insight into how animal-microbiome associations and animal social behaviors evolved.

Symbiopectobacterium in Rhodnius prolixus: evidence for a transitional intracellular symbiosis

Moons T¹, Vogel K², Novakova E¹

¹Department of Parasitology, Faculty of Science, University of South Bohemia, ²Department of Entomology, The University of Georgia

POSTER SESSION 2 - **P02.127**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

It is well established that obligate blood-feeding insects often rely on symbiotic associations with bacteria to supplement essential nutrients, particularly B vitamins, which are deficient in a blood-only diet. Most of these insects harbor obligate symbionts housed within specialized cells or organs known as bacteriomes. Interestingly, kissing bugs (Hemiptera: Reduviidae) appear to diverge from this pattern by maintaining extracellular associations with bacteria localized in the gut lumen rather than in bacteriocytes. Among these potential symbionts, *Symbiopectobacterium* has previously been identified as a symbiont of *Rhodnius prolixus*. This bacterium has also been detected in diverse hosts, including nematodes, fruit flies, leafhoppers, and bullrush bugs, where in the latter it functions as an obligate symbiont residing within bacteriomes.

To investigate the localization and the symbiotic role of *Symbiopectobacterium* in *R. prolixus*, we prepared histological sections from the whole length of the gut (including crop and rectal ampula) dissected from later developmental instars (L4,L5) and adults for fluorescence in situ hybridization (FISH). Probes specific to *Symbiopectobacterium* as well as general eubacterial 16S rRNA probes were used to detect bacterial presence and localization. FISH analysis revealed that *Symbiopectobacterium* is localized intracellularly within the epithelial cells of the posterior midgut. No evidence of

intracellular colonization was observed in the crop or rectal ampula. Unlike the dense and uniform colonization typically observed in specialized bacteriomes, the distribution within the midgut cells of *R. prolixus* is uneven. Not all gut epithelial cells were colonized, and the number of bacteria varied significantly between cells. Most bacteria appeared to accumulate near the gut lumen, although in some cells, bacteria were dispersed throughout the cytoplasm. This intracellular localization sets *Symbiopectobacterium* apart from other facultative symbionts of many other hemipterans, such as stinkbugs, which house beneficial bacteria extracellularly in midgut crypts. Supporting its potential nutritional symbiotic role, genomic analysis of *Symbiopectobacterium* recovered from the *R. prolixus* colony showed complete biosynthetic pathways for multiple B vitamins, including thiamine (B1), riboflavin (B2), pantothenate (B5), pyridoxal (B6), biotin (B7), and folate (B9). Additionally, the genome encodes a functional type III secretion system, which may be important in host cell invasion and intracellular persistence.

These findings suggest that, unlike previously assumed, *R. prolixus* enters a more intimate interaction with *Symbiopectobacterium*. The bacteria are intracellularly localized within the epithelial cells of the posterior midgut, likely representing a transitional form of symbiosis.

Temperature mediates coevolution between parasitoids and symbiont-protected hosts

Vorburger C^{1,2}, Stalder D^{1,2}, Gimmi E^{1,2}, Wallisch J¹, Hudson C¹

¹Eawag, ²ETH Zurich

POSTER SESSION 2 - **P02.126**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Heritable bacterial symbionts often evolve the ability to defend hosts against parasites. Parasites exploiting hosts protected by defensive symbionts are therefore faced with two lines of defense: Those encoded by the host and those conferred by the symbiont. Black bean aphids (*Aphis fabae*) show genotypic variation in resistance to an important natural enemy, the parasitoid wasp *Lysiphlebus fabarum*. Part of the aphid population is additionally protected by infection with the heritable bacterial endosymbiont *Hamiltonella defensa*, which increases resistance to *L. fabarum*. In comparison to the host-encoded resistance, the resistance conferred by *H. defensa* is both stronger and more specific, in that different symbiont strains are unequally effective against different parasitoid genotypes. Experiments and models have shown that in this situation, the symbiont can 'take over' the coevolution with the parasite. However, defensive symbionts tend to have multiple effects on their hosts, of which protection against parasites is just one, raising the possibility that other environmental factors can interfere with the selection by parasitoids. We have learnt – initially by accident – that in black bean aphids, this applies to temperature. In the field, we observed that seasonal increases in

H. defensa prevalence are better predicted by periods of high temperature than by parasitism risk, and in the lab, we observed occasional losses of *H. defensa* in aphid lines reared at low temperature. This suggests that *H. defensa* may protect against heat stress and that vertical transmission of this symbiont is less reliable at low temperatures. Both effects could be confirmed by targeted experiments. This yields the prediction that infections with *H. defensa* should be more prevalent in warmer areas of the host's geographic distribution. We tested this prediction by sampling black bean aphids along a transect from southern Italy to northern Sweden. Indeed, there is a strong latitudinal cline in the prevalence of *H. defensa*, declining from approx. 80% prevalence in the southernmost sites to 0% infection in the northernmost sites. Temperature thus appears to be driving a cline in symbiont-conferred resistance in European black bean aphids. We predict that this has important consequences for coevolution with *L. fabarum*. The relative importance of symbiont-conferred vs. host-encoded resistance will shift along this cline, requiring different counteradaptations by parasitoids in southern vs. northern populations.

The influence of gut microbes on the social brain

Liberti J¹

¹University Of Geneva

POSTER SESSION 2 - P02.131, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The gut microbiota is increasingly recognized for its influence on brain function, with consequences for social behavior. Most studies have focused on the clinical perspectives of modulating the microbiota-gut-brain (MGB) axis for the treatment of neurodegenerative diseases and behavioral dysfunctions, using experimental models of human genetics and disease. However, it is still unclear to what extent the MGB axis modulates social interactions across the tree of life and whether the proximate mechanisms regulating these microbiota-host interactions are conserved. Social bees provide unique models to advance our understanding of the MGB axis and its role in shaping social interactions, as they exhibit complex social behaviors at both the individual and collective levels.

To study the effects of bacterial symbionts on brain physiology and social behaviors, we manipulated the composition of the honeybee

gut microbiota and coupled these manipulations with automated behavioral tracking. We discovered that the gut microbiota increases the frequency and specialization of social interactions among bees, and that these effects are associated with changes in gene expression and an increase in the concentration of specific metabolites in the bee brain. We are currently performing follow-up studies to disentangle the relative contributions of individual gut members to distinct social behaviors and further unravel the molecular mechanisms mediating these interactions. Additionally, we are exploring the evolutionary conservation of microbiota – social brain interactions across bee lineages and assessing their ecological significance. Our results suggest that the gut microbiota plays an important role in shaping the social organization of bees, with potential consequences for their ecological success and the services they provide as pollinators.

The Living Fossils of Symbiosis: Wolbachia Genes in *Rhodnius prolixus*

Novakova E¹, Tarabai H², Vogel K³

¹Faculty Of Science, University Of South Bohemia In Ceske Budejovice, ²Central European Institute of Technology (CEITEC), Czech Republic, ³Entomology Department, The University of Georgia, Athens, GA

POSTER SESSION 2 - **P02.140**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The advent of high-quality arthropod genome assemblies enables the discovery of evolutionary relics from past symbiotic relationships. A near-chromosome-level assembly of the *Rhodnius prolixus* genome (in prep.) reveals 129 horizontally transferred genes or gene fragments of Wolbachia origin; substantially more than the 27 genes across 85 regions reported in the earlier assembly (GCA_000181055). Our results highlight the compact nature of nuclear Wolbachia transfers, with 107 genes clustered within a single 176 Kb region. Phylogenetic analysis indicates their origin from the Wolbachia F supergroup. Unlike in other hosts (e.g., bean beetle, pine sawyer beetle, fruit fly, or tsetse fly), where Wolbachia-derived regions progressively decay, over 50% of these genes are actively transcribed in *R. prolixus*, often in a tissue-specific manner, with strong

enrichment in ovarian expression. The most represented functional categories among transcribed genes include cell wall/membrane/envelope biogenesis (COG category M, n=15) and replication, recombination, and repair (COG category L, n=11). The presence and expression of genes encoding transposases, DNA polymerase I, reverse transcriptase, helicases, and mismatch repair proteins (20 total; 11 expressed) suggest a potentially functional Wolbachia-derived machinery for genome plasticity and maintenance. Codon usage patterns closely match host preferences, implying co-option of Wolbachia genes by the *Rhodnius* genome. Functional validation through gene knockdowns is however essential to assess their roles in host-microbe interactions.

The microbiome of suprapubic and sternal scent glands of wild tamarins suggests microbes play a key role in olfactory communication

Carboni S¹, Poirier A¹, Peralta-Aguilar A³, Erkenwick Watsa M², Erkenwick G³, Melin A^{1,4,5}

¹Department of Anthropology & Archaeology, University Of Calgary, ²San Diego Zoo Wildlife Alliance,

³Field Projects International, ⁴Department of Medical Genetics, University of Calgary, ⁵Alberta Children's Hospital Research Institute, University of Calgary

POSTER SESSION 2 - **P02.122**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

The microbiome of mammalian scent glands is increasingly realised to play a key role in olfactory communication. Defining these glandular microbiomes in wild species is essential for understanding the complex evolution of host-microbe interactions and their influence on scent production. We studied the microbiome of suprapubic and sternal scent glands in two sympatric species of wild primates in Peru: saddleback tamarins (*Leontocebus weddelli*), and emperor tamarin (*Saguinus imperator*). Sternal and suprapubic glands have similar histology, but the suprapubic gland is used more frequently for scent marking behaviors, possibly favouring more microbial exchange through environmental contact. We aimed to: 1) profile sternal and suprapubic glandular microbiomes of both primate species, focusing on microbial taxa and metabolic pathways related to odor production, and 2) determine if suprapubic glands had higher diversity and distinct composition of odor-related taxa and pathways compared to the sternal glands.

We collected 39 swabs of suprapubic glands (19 saddleback, 20 emperor) and 37 swabs of sternal glands (18 saddleback, 19 emperor). We generated metagenomic libraries and used short-read DNA shotgun sequencing on an Illumina NovaSeqX. We profiled the glandular microbiome of the two tamarin species by calculating relative abundances and prevalence of microbial taxa, and we assessed differences in microbial diversity and composition between gland types. We used GLMMs to analyze alpha-diversity (Shannon and Chao1 indices), PERMANOVA to analyze beta-diversity (robust Aitchinson index), and ANCOM-BC tests to

examine differences in abundances of taxa and pathways.

The microbial profile of our entire datasets, comprising suprapubic and sternal glands of both *L. weddelli* and *S. imperator*, included 74.5% of bacterial taxa and 25% of eukaryotes. We identified the same 18 odor-associated microbial taxa in each tamarin species, mainly in genera *Staphylococcus* and *Corynebacterium*, and 26 shared pathways, such as pyruvate fermentation and amino acid metabolism. Suprapubic glands differed in beta-diversity and had lower Shannon alpha-diversity relative to sternal glands, and the effect was more pronounced in *L. weddelli*. The glands of *L. weddelli* also differed in taxonomic composition, with odor-related taxa such as *Corynebacterium atypicum* and *Corynebacterium frankenforstense*, more abundant in suprapubic glands.

Our results provide new insight into the taxonomy and the metabolic activity of the glandular microbiome, reinforcing hypotheses of their key role in odor production. The significant differences in microbial diversity and composition between sternal and suprapubic glands of *L. weddelli* suggest that the microbiome of suprapubic glands play a more specialized role in odor production than the sternal glands. This is in contrast to the glands of *S. imperator*, highlighting potential species-specific variations in glandular microbiome adaptations.

This study offers a novel perspective into the role of microbiomes in shaping the odor of wild animals, uncovering microbial taxa and pathways similar to those found in humans and other mammals, and highlighting putative microbial adaptations for olfactory communication.

The rat gut microbiome is affected by indirect genetic effects from social partners, which could drive rapid evolutionary change

Baud A¹, Tonnele H¹, Chen D², Knight R², Palmer A²

¹Centre For Genomic Regulation, ²University of California San Diego

POSTER SESSION 2 - **P02.137**, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Mammalian hosts have evolved mechanisms to actively filter and select the symbiotic microbes that live inside their gut. This ongoing evolutionary process has left signatures in the form of associations between host genotypes and gut microbiome traits. In addition, mammals exchange gut microbes through vertical and horizontal transmission. This ecological process can now be observed directly by characterising the microbiome at the level of bacterial strains and tracking strain transmission across hosts.

We hypothesised that the coupling of these evolutionary and ecological processes would result in indirect genetic effects on the microbiome (Mic-IGE), whereby microbiome traits of one individual are affected by genotypes of other, conspecific individuals (social partners). Based on established evolutionary theory on indirect genetic effects, we further hypothesised that Mic-IGE would increase the total genetic variance of microbiome traits, which would greatly increase the potential for evolution by natural selection.

To test these hypotheses, we studied host/microbiome interactions in outbred “Heterogeneous Stock” (HS) laboratory rats

housed in groups of two or three. HS rats show high levels of genetic diversity and heterozygosity, and the genetic variants segregating in the HS are natural, inherited from the wild ancestors of the population. In addition, like their wild conspecifics, HS rats have a complex gut microbiome and they express social behaviours (e.g. allo-coprophy) favouring gut microbial transmission between social partners.

We sequenced and profiled the gut (cecal and fecal) microbiomes of thousands of HS rats using various, complementary sequencing techniques. The genotypes of the rats were available from collaborators. We carried out an in-depth analysis of direct and indirect genetic effects on the microbiome, focusing on Mic-IGE arising between adolescent and adult rats sharing a cage.

We found pioneering evidence of Mic-IGE in this experimental setting. We further demonstrated that, as expected, Mic-IGE greatly increased the total genetic variance. We integrated these empirical results with state-of-the-art evolutionary theory on indirect genetic effects to conclude that Mic-IGE could drive rapid evolutionary change in host/microbiome interactions.

Tissue Type drives plant-associated bacterial community structure more than geographic location: Insights from Antarctica and Patagonia

Mathew S^{1,2}, Saikkonen K¹, Helander M², Nissinen R²

¹Biodiversity Unit, University Of Turku, ²Department of Biology, University of Turku

POSTER SESSION 2 - P02.151, EXPO AREA, August 19, 2025, 5:00 PM - 7:00 PM

Plant-associated bacterial communities are crucial in understanding evolutionary adaptations of plants to the environment and changing climatic conditions. Plant recruit bacteria that contribute nutrition, disease resistance and stress tolerance based on biotic and abiotic conditions, ensuring the host plant survival. Plant bacterial communities are often described from tropical and temperate environments. However, bacteria associated with plants in polar regions remain elusive, especially from southern polar regions. This is particularly intriguing since plant-bacterial adaptations in vascular plant *Deschampsia antarctica* in Antarctica gives insights into the evolutionary adaptations of primary successors in an ecological community. With changing climatic conditions, Antarctica is being warmer and there can be expansion of range of species. The present study accounts for the bacterial communities in *Deschampsia* in Patagonia and Antarctica and understands their importance in these extreme environments. Leaf, root and phyllosphere samples were collected from 4 different populations in

Antarctica and 6 different populations in Patagonia. DNA was extracted from each tissue sample and gene libraries were prepared by amplifying V6-V8 regions of the 16S rRNA gene. Using Illumina MiSeq platform, the 16rRNA gene sequencing was done to find bacterial communities. Using phyloseq, DADA2 and microbiome packages in R, data analyses was performed. In both locations, root endophytic community and leaf endophytic community were diverse than phyllosphere communities. But remarkably, we found that the bacterial communities are specific to tissue type rather than geographical locations. This strongly shows the evolutionary relations between plant tissue niche and the bacterial communities. In addition, certain bacterial taxa were found to be specific to Antarctica and Patagonia. This could indicate their special significance related to niche, geographical location or climatic condition. This needs to be further investigated to understand their functional relevance based on geographical location and evolutionary significance.

A genome-eroded symbiont with a transcriptional response to the host's needs

⁴Lernwerft Club of Rome Schule Kiel

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

Symbiotic bacteria in long-term host associations frequently undergo extreme genome reduction. While they retain genes beneficial to the host, their repertoire of transcription factors is severely reduced. Here, we investigate the gene expression of genome-eroded symbionts across life-stages and species of a beetle subfamily: the reed beetles (Coleoptera: Chrysomelidae, Donaciinae). These symbionts feature a small genome (~0.5 Mb), encoding for 9-10 essential amino acid biosynthesis pathways, 0-2 pectinases, and 4-5 transcription factors. Across life-stages, symbionts adjusted gene expression to meet the hosts' nutritional demands, upregulating amino acid (AA) biosynthesis in larvae, while expression and enzymatic activity of host and symbiont enzymes involved in plant cell-

wall break-down increased in the folivorous adults. Although the upregulated symbiont genes during larval stages are enriched for AA biosynthesis genes across all species, different AA pathways were upregulated across genera. These differences correspond in part to the presence/absence of different AA pathways in the symbiont's genomes and differences in the cocoon's amino acid composition, indicating a symbiont's contribution to cocoon building. Thus, reed beetle symbionts show a functionally consistent transcriptional response to host demands, while showcasing transcriptomic changes related to differential gene losses, highlighting the regulatory potential of long-term coevolved symbionts despite severely reduced genomes.

Could co-evolution explain Wolbachia-driven loss of pesticide resistance in spider mite populations?

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

Background: The ubiquity of Wolbachia in arthropods and its ability to manipulate host reproduction have attracted considerable attention for its use as a gene drive vehicle to control pest populations. Such control strategies are generally based on genes carried by Wolbachia itself, but their success also hinges on the potential effect of this symbiont on the dynamics of host genes, such as those responsible for adaption to particular environmental pressures, including other control strategies. We addressed this issue with a combination of theoretical and experimental approaches.

Methods and Results: We first showed theoretically that, given the range of fitness effects that Wolbachia can have on their hosts, even transient association between different host genotypes and this endosymbiont may lead to the fixation or the elimination of host alleles.

Then, we performed experimental evolution of spider mite populations sharing the same genetic background but carrying or not a single nucleotide mutation conferring resistance to the pesticide etoxazole, and infected or not with Wolbachia. We found that the host genotype alone (fully resistant vs. fully susceptible populations) did not affect the spread of Wolbachia, nor did Wolbachia infection alone (fully infected vs. fully uninfected populations) affect the dynamic of the resistance allele. However, we found variable dynamics of the resistant allele when Wolbachia was simultaneously invading the host populations: the frequency of the resistance allele remained constant when Wolbachia infection was associated

with susceptible hosts at the beginning of experimental evolution, whereas it dropped when the symbiont originated from resistant hosts.

Finally, we measured the effect of Wolbachia infection on the life history traits of different host genotypes (homozygous susceptible or resistant, or heterozygous), as well as the effect of the pesticide resistance allele on Wolbachia-induced cytoplasmic incompatibility (CI). Preliminary results show that, in compatible crosses, Wolbachia infection increases the growth rate only of hosts carrying the etoxazole resistance allele, and, in incompatible crosses, Wolbachia-infected resistant males induce lower CI levels than Wolbachia-infected susceptible males.

Conclusions and Perspectives: One possibility to explain such genotype-specific fitness effects of infection, and observed dynamics of the resistance allele, hinges upon the long co-evolutionary history between this allele and Wolbachia in the host populations. Even though Wolbachia infection was introgressed via repeated backcrosses from the susceptible populations into the resistant ones, ensuring the same strain initially infected all populations, this was done more than a hundred host generations before performing the experiments. Although these results call for further investigations to determine whether and how co-evolution would explain this outcome, they also undoubtedly show that Wolbachia can play an important role in the evolutionary trajectories of its hosts.

Dissecting the fitness components of nitrogen-fixing rhizobia throughout their symbiotic life cycle

Granada Agudelo M¹, Ruiz B¹, Remigi P¹, Capela D¹

¹Laboratoire des Interactions Plantes Microbes Environnement (LIPME), Université de Toulouse, INRAE, CNRS

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

Living organisms are surrounded by complex microbial communities, where interactions, ranging from mutualistic to pathogenic, influence their physiology, development, and ecological success. These associations span from transient encounters to intimate symbioses, shaping evolutionary trajectories on both sides. Among the most well-studied mutualistic interactions is the nitrogen-fixing symbiosis between legume plants and rhizobia. During this interaction, bacteria are hosted in specialized root organs called nodules, where they provide organic nitrogen to the host in exchange for carbon compounds. This mutualism enhances the fitness of both partners. From the rhizobial perspective, fitness comprises multiple components that are important at different life cycle stages, including: (i) proliferation and survival in the soil and rhizosphere, (ii) nodulation efficiency and competitiveness, (iii) proliferation and survival within nodules, and (iv) release from nodules during senescence. The role of host-related factors in shaping rhizobial fitness has been deeply studied. However, the contribution of interbacterial interactions to rhizobial fitness and evolutionary dynamics is still poorly understood.

In this study, we examined how interactions among nine beta-rhizobial strains affect their fitness during symbiosis with the legume plant *Mimosa pudica*. We first characterized the fitness of each strain in single-inoculation experiments, measuring

nodulation rate, proliferation within nodules, and nitrogen fixation. These traits were used to predict the outcomes of pairwise co-inoculations under the assumption that no interaction occurs between strains. We then performed 36 pairwise co-inoculation experiments to test these predictions. In most pairs, observed fitness differed from predictions, indicating that ecological interactions among rhizobial strains are common. Nodulation competitiveness, defined as the ability to form nodules during co-inoculation, was the primary factor modulating interactions among strains. This finding highlights the role of early infection steps as a bottleneck for rhizobial selection. However, we also identified a case where co-inoculation affected rhizobial proliferation within nodules, suggesting indirect, potentially host-mediated, interactions during later stages of symbiosis.

Additionally, we tested more complex communities composed of six or eight strains to assess the transitivity of competitive interactions. Fitness rankings established from pairwise experiments predicted outcomes in these multistrain communities, suggesting that, in this system, higher-order interactions are either negligible or have only a limited effect on rhizobial fitness.

Overall, this work provides a detailed account of the ecological processes governing symbiotic fitness in simple communities of plant-mutualistic bacteria.

Eco-evolutionary context shapes fitness and diversity in a protective symbiosis

Drew G^{1,2}, King K^{2,3}

¹Eawag, ²University of Oxford, ³University of British Columbia

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

Microbial symbionts protect many host species against pathogens. Ecological and coevolutionary context can shift rapidly in these networks of interacting species, and how such shifts affect the trajectories of each player remain important questions. When under attack from a coevolving pathogen, will hosts respond by depending on their symbionts, or by investing in their own defence mechanisms? In turn, if a pathogen becomes extinct in a community, how will the interaction between host and symbiont proceed? To address such

questions, we experimentally evolved a community of genetically-diverse nematode hosts, protective symbionts (*Enterococcus faecalis*) and pathogens (*Staphylococcus aureus*) under different eco-evo contexts. After 15 host generations we report effects on host dependence, pathogen virulence and symbiont diversity. Our results highlight inherent complexity in the evolution of protective symbioses and hold relevance for programs that introduce symbionts for pathogen control.

Evolutionary dynamics of nested symbiosis in *Aphrodes* leafhoppers

Andriienko V^{1,2}, Franco D^{2,3}, Stroiński A⁴, Łukasik P⁵, Michalik A²

¹Doctoral School of Exact and Natural Sciences, Jagiellonian University, ²Institute of Zoology and Biomedical Research, Jagiellonian University, ³Terrestrial Ecology Unit, Ghent University, ⁴Museum and Institute of Zoology, Polish Academy of Sciences, ⁵Institute of Environmental Sciences, Jagiellonian University

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

Background: Symbiotic associations with microbes have played a central role in insect diversification and ecological success. In Auchenorrhyncha – a group that includes leafhoppers, planthoppers, spittlebugs, and cicadas – these associations originated ~300 million years ago when their common ancestor acquired two bacterial symbionts: one from the phylum Bacteroidetes and another from the phylum Proteobacteria (class Betaproteobacteria). Descendants of these ancestral symbionts persist in many modern lineages, though some clades have since replaced or supplemented them with new partners, leading to remarkable diversity in symbiotic systems. Leafhoppers of the genus *Aphrodes* exhibit a particularly intriguing system that illustrates both long-term evolutionary conservatism and ongoing diversification of symbionts. In addition to the two ancient symbionts – *Sulcia* (Bacteroidetes) and *Nasuia* (Betaproteobacteria) – our research reveals a third partner, which is the gammaproteobacterial symbiont *Sodalis* localized within the cytoplasm of *Sulcia* cells. This represents a rare and highly unusual case of nested symbiosis, where one bacterial symbiont lives inside another.

Materials and Methods: To explore this unique nested symbiosis, we used light and electron microscopy to localize *Sodalis* in the *Aphrodes* body. To get a broad picture of microbial diversity, we generated 16S rRNA amplicon data for 112 individuals representing 3 *Aphrodes* species, collected across 16 populations from mainland and island sites in Europe. Additionally, we performed metagenomic sequencing on a subset of 30 individuals. Assembly and contig clustering were used to detect co-occurring *Sodalis*

strains, and phylogenomic analyses, based on conserved, informative genes, were conducted to explore their evolutionary relationships.

Results: Microscopy revealed that *Sodalis* is localized within *Sulcia* cells, both in specialized bacteriomes and during transovarial transmission, suggesting its essentiality for the host and advanced intracellular adaptation. Amplicon data revealed population-level variation in *Sodalis* presence, with multiple strains often co-occurring within individual hosts. Metagenomic analyses confirmed the presence of distinct *Sodalis* strains co-occurring in several hosts. The *Sodalis* phylogeny was inconsistent with the host tree, suggesting multiple acquisition events or ongoing strain replacement, possibly involving horizontal transmission. Meanwhile, *Sulcia* and *Nasuia* genomes remain stable and highly reduced, retaining complementary pathways for essential amino acid biosynthesis. In contrast, *Sodalis* retains a broader metabolic range, consistent with a more recent integration into the symbiotic system.

Conclusions: The persistence of multiple *Sodalis* strains within individual hosts, along with their unique nested arrangement inside *Sulcia*, highlights the evolutionary dynamics of the *Aphrodes* symbiotic system – one that merges ancient partnerships with ongoing microbial exchange. This system offers a valuable model for investigating nested symbiosis, co-residence of symbionts, and symbiont replacement within a stable host framework. Our work underscores the importance of strain-level resolution in symbiosis research and illustrates the flexibility of microbial partnerships in shaping insect adaptation and diversification.

Infection dynamics of endosymbionts that manipulate arthropod reproduction

Brenninger F¹, Zug R², Kokko H²

¹University of Bern, ²Johannes Gutenberg-University Mainz

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

Endosymbionts capable of altering host reproduction are widespread among arthropods. These reproductive manipulations – including male-killing, feminisation, cytoplasmic incompatibility, parthenogenesis induction, and sex allocation distortion – have independently evolved across a diverse range of microorganisms, including bacteria, fungi, and some viruses. Whilst all these manipulations are adaptations of the symbiont to increase its spread within host populations, they differ in their mechanistic underpinnings and resulting infection dynamics.

Our study presents a unified modelling framework that captures the key elements required to describe the effect of each reproductive manipulation. This approach not only highlights fundamental insights from previous research on each manipulation but also enables direct comparisons of the infection dynamics resulting from different strategies. We derive invasion criteria for all possible combinations of manipulative endosymbionts – including previously unexplored scenarios – demonstrating the

conditions under which a rare manipulating endosymbiont can successfully invade a population that is either uninfected or already harbouring another reproductive manipulator. Additionally, we show when the spread of a reproductive manipulator can differ between haplodiploid and diplodiploid hosts, and when it does not, highlighting the importance of interactions between host and symbiont biology for endosymbiont spread. Intriguingly, our framework reveals that reproductive manipulations which, in principle, might be expected to have superior invasion prospects are not necessarily the most prevalent in nature. This suggests that successful spread of a reproductive manipulator is also strongly linked to the underlying physiological mechanisms of each manipulation and other aspects impacting interspecific host switches. These findings highlight the drivers of endosymbiont spread and persistence, which are essential to appreciating their evolutionary influence on arthropods and advance our understanding of host-symbiont coevolution.

Pushing the limits of genome reduction: evolution of ancestral planthopper symbiont genomes

Michalik A¹, Castillo Franco D^{1,2}, Deng J^{1,3}, Stroiński A⁴, Szklarzewicz T¹, Prus-Frankowska M¹, Łukasik P¹
¹Jagiellonian University, ²Ghent University, ³Doctoral School of Exact and Natural Sciences, Jagiellonian University, ⁴Polish Academy of Sciences

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

Background: Ancient heritable nutritional endosymbiotic bacteria found in sap-sucking hemipterans are characterized by extremely reduced genomes and strict maternal transmission. These symbionts, essential for supplementing amino acids absent from the insect diet, have lost over 90% of their ancestral genes, resulting in some of the smallest bacterial genomes. After the intense genome reduction, symbionts reached a stable evolutionary stage in which their remaining genes, critical for the host-symbiont relationship, maintain highly conserved content, structure, and organization. However, in multiple host lineages, these tiny genomes undergo further dynamic changes, including further genome reduction, rearrangements, and fragmentation. In our study, we investigated these evolutionary processes in planthoppers (infraorder Fulgoromorpha), a diverse group of Auchenorrhyncha that are associated with two ancient, bacterial symbionts with highly reduced genomes: *Candidatus Sulcia muelleri* and *Candidatus Vidania fulgoroidea*, for approximately 263 million years.

Materials and methods: Metagenomic libraries from 149 globally collected planthopper species were sequenced using Illumina. *Sulcia* and *Vidania* genomic fragments were identified in Megahit metagenomic assemblies using BLAST tools and previously curated reference genomes. Annotations of these highly divergent genomes, especially of *Vidania* characterized by extreme sequence evolutionary rates, were done through iterative HMMER searches using collections of hand-curated gene alignments. Genome organization was reconstructed based on annotations and comparison with the reference *Sulcia* and *Vidania* genomes from *Oliarus filicicola* OLIH.

Results: Our results showed that *Sulcia* and *Vidania* are broadly distributed

across planthopper species. Based on rRNA sequences from metagenomic data, we identified *Vidania*, typically accompanied by *Sulcia*, in 87 out of 149 species, representing 15 of 19 surveyed families. We reconstructed 65 *Sulcia* and 68 *Vidania* circular genomes, with sizes ranging from 137–180 kb for *Sulcia* and 50–137 kb for *Vidania*. While *Vidania* genomes largely preserved ancestral gene order, approximately 21% of *Sulcia* genomes exhibited structural inversions.

Our comparative analyses revealed that the ancestral gene sets of *Sulcia* and *Vidania* symbionts comprised at least 164 and 169 genes, respectively. We detected no gene gains, but gene losses were common, particularly in *Vidania*, indicating ongoing genome erosion that primarily affects genes involved in genetic information processing and metabolism. The two smallest *Vidania* genomes from *Saccharosydne* sp. (50 kb) and *Malenia bosnica* (52 kb), exhibit striking convergence in gene content despite evolving independently, retaining core genes such as rRNA genes, ribosomal proteins, and polymerase subunits, while lacking all aminoacyl-tRNA synthetases and most amino acid biosynthesis pathways except for phenylalanine.

In some planthopper lineages, the ancestral *Sulcia* genome has split into multiple genetically and cytologically distinct but interdependent lineages that together function as a single symbiont.

Conclusions: Our study reveals the remarkable genomic diversity and evolutionary dynamics of the ancient symbionts *Sulcia* and *Vidania* in planthoppers. These findings enhance our understanding of the processes and drivers of genomic evolution of ancient symbionts and their co-evolution with host species.

Spread of Wolbachia in haplodiploids is driven by extensive rewiring of female reproductive physiology

Van Reempts E¹, Gignoux G¹, Kauai Pereira F¹, Wybouw N¹

¹Ghent University

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

Maternally inherited symbionts, such as Wolbachia, manipulate host reproduction to promote their transmission. Recent work has shown that Wolbachia can distort sex allocation in haplodiploid hosts by increasing egg fertilization rate, a reproductive phenotype hereafter referred to as Sd. However, the mechanisms underlying Sd, and the eco-evolutionary implications for host-symbiont interactions, remain poorly understood.

To address this, we first mapped the pleiotropic effects of an Sd-inducing Wolbachia infection in haplodiploid *Tetranychus urticae* mites. Using near-isogenic infected and cured lines, we quantified the impact of infection on fecundity, hatch rate, developmental time, and egg size. Maternal transmission efficiency of the Sd-inducing Wolbachia variant was also quantified. As Wolbachia-mediated effects might be contingent on host age, we tested the influence of maternal age on these measurements. Parametrized individual-based simulations were performed to evaluate these effects on the spread of Wolbachia within host

populations. We subsequently performed comparative genomics and transcriptomics to further uncover the underpinning mechanisms of Sd.

Our empirical and theoretical work show that Sd is associated with complex coordinated shifts in host life-history traits that skew sex ratios toward infected females, strongly promoting Wolbachia transmission. Of note, our simulations reveal that even modest shifts in developmental timing and hatch rate dramatically facilitate Wolbachia spread within haplodiploid populations. Additionally, genomic analyses of our Wolbachia variant are concurrent with theoretical work that predicts that Sd facilitates infection persistence upon loss of cytoplasmic incompatibility. Host transcriptomics identified several candidate genes potentially involved in Sd, providing a first insight into the molecular basis of this reproductive phenotype. Together, these experiments uncover novel mechanistic insights into how Wolbachia spread and are maintained in haplodiploid populations.

Symbiosis-mediated gene transfer in early-diverging Metazoan

¹Department of Biology, Lund University, ²Department of Chemistry and Biochemistry, Gonzaga University, ³Department of Biology, Bates College, ⁴Department of Biological Sciences, University of Alberta, ⁵Science for Life Laboratory, Department of Biology, Lund University

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

In animals, new phenotypic traits typically emerge through gene duplication, splice variation, recombination, or gene loss. Lateral Gene Transfer (LGT), the movement of genetic material across species boundaries, offers an alternative path to acquire new functions. While common in microbes, LGT is rare in animals due to germline segregation. However, animals with asexual lifestyles and diverse microbial communities, such as sponges, have increased potentials for host-microbe gene exchange.

Many sponges inhabit low-oxygen environments and display remarkable tolerance to hypoxia. Here, we identify a possible mechanism for hypoxia tolerance in freshwater sponges through anaerobic respiration. Microbial eukaryotes and some bacteria synthesize the anaerobic cofactor rhodoquinone (RQ) using the enzyme RquA. RQ facilitates electron transfer between Complex I and Complex II of the mitochondrial respiratory chain whereby fumarate, and not oxygen, is the terminal electron acceptor. We identified an ortholog of RquA in multiple freshwater sponges, likely acquired via LGT from a microbial eukaryote. The absence of RquA in marine

sponges suggests that this gene transfer event occurred in Spongillidae following their divergence from marine lineages.

Quinone profiling using liquid chromatography-mass spectrometry revealed that while marine sponges primarily contain UQs with traces of RQs, freshwater sponges exhibit significantly higher RQ levels, likely synthesized from UQ via the *rquA* gene. Exposure of adult freshwater sponges to 2% O₂ resulted in subtle *rquA* upregulation after 72 hours, suggesting a potential role in long-term adaptation to hypoxia. Phenotypic assessment with confocal microscopy showed no major structural changes under hypoxia, including the integrity of the osculum and choanocyte chambers, thus indicating strong tolerance to hypoxia.

Our results suggest that freshwater sponges have acquired a functional *rquA* gene via LGT, enabling endogenous RQ synthesis as an adaptation to low-oxygen environments. This finding expands our understanding of LGT in animals and highlights the potential role of microbial symbioses in shaping animal metabolism and ecological resilience.

The dynamics of coral symbiosis across latitude; opportunities and challenges of coral range expansion in a warming world.

McIlroy S¹, Brennan J², Conti-Jerpe I³, Kim T⁴

¹The Chinese University Of Hong Kong, ²The University of Hong Kong, ³Lingnan University, ⁴Jeju Research Institute

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

The tight nutritional recycling between corals and their photosynthetic intracellular algae is among the most successful and prolific associations to have evolved as evidenced by the extensive coral reef structures within relatively nutrient poor tropical waters. Yet the warm, eutrophic, stable conditions which favoured this association is shifting. In the tropics, temperature anomalies that exceed a corals' thermal maxima have become the norm, while at poleward range edges thermally suitable habitats for corals appear to be extending, with cases of coral expansions into higher latitudes. Here we consider how the reliance of corals on their algal symbionts restricts and/or enhances their latitudinal ranges. We generated

thermal performance curves of physiological data from three coral genera and their associated symbionts collected from four locations in the Northwest Pacific. These data indicate that acclimation/adaptation to thermal extremes experienced at high latitudes may be limited by symbiont physiology, but that symbiotic associations show flexibility across the range. Furthermore, we present stable isotope data from a subset of locations to examine the role of trophic plasticity, the ability of corals to shift away from their reliance on symbiont derived nutrients, in understanding the limits on current and ongoing coral range expansion.

The role of *Wolbachia* in reproductive isolation and speciation in *Drosophila paulistorum*

Ekström L¹, Papachristos K¹, Miller W², Klasson L¹

¹Molecular evolution, Department of Cell and Molecular Biology, Science for Life Laboratory, Uppsala University, ²Lab Genome Dynamics, Department Cell & Developmental Biology, Center for Anatomy and Cell Biology, Medical University of Vienna

MEETING ROOM 116, August 21, 2025, 10:30 AM - 12:30 PM

Wolbachia is a genus of maternally inherited endosymbiotic bacteria infecting hosts of the Arthropoda and Nematoda phyla. The broad distribution and wide host range are mainly attributed to the bacterium's remarkable diversity in strategies to manipulate host biological processes, enabling it to spread into and persist in populations. Among the most well-studied phenotypes associated with *Wolbachia* infection is the ability to influence host reproduction by inducing cytoplasmic incompatibility (CI). In *Drosophila*, CI is induced by a modification of the sperm during spermatogenesis, resulting in embryonic lethality upon mating with an uninfected female (unidirectional CI) or a female infected with an incompatible *Wolbachia* strain (bidirectional CI). Viable offspring are produced only in matings with partners possessing a compatible factor to restore the modification. In populations harboring multiple, bidirectionally incompatible *Wolbachia* strains, reproductive isolation and reduced gene flow between subpopulations infected with incompatible *Wolbachia* suggest a potential role for the endosymbiont in facilitating sympatric host speciation.

The *Drosophila paulistorum* superspecies, comprising six reproductively isolated but geographically overlapping incipient species, infected with highly similar *Wolbachia* strains, offers a unique opportunity to study the speciation process and assess the role of *Wolbachia* in driving this process. *D. paulistorum* differs from its close relatives in the willistoni group by harboring an obligate, rather than facultative, *Wolbachia* infection. Moreover, *Wolbachia* is associated with both pre- and post-mating isolation in *D. paulistorum*. Reduction in *Wolbachia* titer alters male pheromone profiles critical for

semispecies-specific mate recognition and crosses over the semispecies boundaries results in hybrid lethality and male sterility. Beyond reproductive effects, *Wolbachia* impacts a broad range of biological processes, including immunity, metabolism, and muscular functions in *D. paulistorum*, indicating the impact of the infection is by no means restricted to processes related to reproduction.

Little is known about the genomic differences between *Wolbachia* infections in different species of the willistoni and saltans groups, and what designates the obligate association in *D. paulistorum*. An intriguing hypothesis is that the CI-inducing genes, *cifA* and *cifB*, present in *D. paulistorum* but absent in other members of the willistoni subgroup, contribute to reproductive isolation and consequently to the incipient speciation process. We sequenced *Wolbachia* genomes from multiple semispecies of *D. paulistorum* and related species from the willistoni and saltans groups along with their corresponding *Drosophila* host genomes. Through phylogenomics and comparative genomics, we uncover both sequence-level and structural differences in *Wolbachia* across and within species and semispecies. We analyze candidate genes involved in host interaction, investigate patterns of genome reduction associated with the obligate symbiosis in *D. paulistorum*, and assess phylogenetic congruence among *Wolbachia* and host genomes. Our aim is to provide insights into the impact of *Wolbachia* on host evolution, advance understanding of the incipient speciation process in the *D. paulistorum* superspecies, and uncover genomic features underlying the transition from facultative to obligate endosymbiosis.

Unraveling the mechanisms driving transitions to parthenogenesis in a *Wolbachia*-infected ladybug

Jecha K¹, Freitas S¹, Lecompte E², Parthuisot N², Dumas Z¹, Schwander T¹, Magro A²

¹University of Lausanne, ²University of Toulouse

MEETING ROOM 116, August 20, 2025, 10:30 AM - 12:30 PM

Parthenogenesis in animals is a reproductive mechanism enabling females to produce offspring without a mate. While the evolutionary advantages behind the transition from sexual reproduction to parthenogenesis are well understood, the specific mechanisms by which transitions occur in each case remain unclear. Hybridization, infection by a parthenogenesis-inducing bacterial endosymbiont, and odd-numbered polyploidization are traits that are often associated with transitions to parthenogenesis in arthropods. With these observations in mind, we investigated the origin of the first case of parthenogenesis in a ladybug by generating a long-read genome assembly of *Nephus voeltzkowi* individuals from one of several recently discovered parthenogenetic populations to uncover the presence of any of these traits. We found a rare combination of all three traits as parthenogenetic individuals appear to be of

hybrid origin, infected with *Wolbachia* bacteria, and possess triploid genomes, whereas the sexual populations are diploid and lack these traits. We performed a *Wolbachia* elimination experiment to determine the role that the infection plays in the reproduction of the parthenogenetic *N. voeltzkowi*. The experiment demonstrated that the elimination of *Wolbachia* resulted in a reduction in egg hatching rate followed by a drastic reduction in egg production among treated females. This suggests that infection by these bacteria is necessary for successful reproduction in the parthenogenetic females and *Wolbachia* may even play a two-part role by facilitating egg laying and early embryo development. Understanding the traits underlying transitions to parthenogenesis and their relation to each other will provide new insights into the diversity, mechanisms, and evolutionary consequences of alternative reproductive modes in animals.

A new method for identifying local adaptation

Do O I¹, de Villemereuil P^{2,4}, Gaggiotti O³, Goudet J^{1,5}

¹University Of Lausanne, ²Institut de Systématique, Évolution, Biodiversité (ISYEB), École Pratique des Hautes Études,, ³University of St Andrews, ⁴Institut Universitaire de France (IUF), ⁵Swiss Institute of Bioinformatics

*POSTER SESSION 1 - **P01.287**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM*

Climate change imposes novel selective pressures either by rising selection's magnitude or direction, increasing the need for robust methods to identify populations and traits keeping up with these changes. Studying current and past local adaptation will allow us to draw hypothesis on what types of traits are able to adapt. Accurate differentiation between adaptive and neutral evolutionary processes is therefore essential for creating the background necessary predictive evolutionary genomics. On that aim, we introduce LAVA, a novel statistical approach that uses estimates relatedness through allele-sharing in genome-wide markers, carefully integrated into a genetic population model to overcome existing limitations in quantifying adaptive divergence. While traditional QST-FST

comparisons fail to account for complex demographic histories and deviations from the island model, thereby generating inflated Type I error rates, LAVA incorporates between- and within-population relatedness matrices to include demographic structure. Through comparative analysis with previous methods and using simulated data under both neutral conditions and various selective regimes, we demonstrate that LAVA maintains appropriate statistical calibration across diverse population structures while keeping high statistical power to detect adaptive divergence. We further validate LAVA's relevance through a meta-analysis of empirical datasets spanning multiple taxa, revealing patterns of trait responses to selection.

A Tale of Two Seas: Local Adaptation and Osmoregulation in the copepod *Acartia tonsa*

Hahn A¹, Nascimento Schulze J¹, Avgerinou G¹, Bayer T¹, Renz J², Brennan R¹

¹Geomar Helmholtz Centre for Ocean Research Kiel, ²Senckenberg Society for Nature Research

POSTER SESSION 1 - **P01.269**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Understanding the genomic and physiological basis of local adaptation is essential for predicting species' responses to environmental change. Salinity—a key environmental factor shaping marine biodiversity—is rapidly shifting due to climate change, especially in marginal seas like the Baltic. Yet, the mechanisms enabling species to tolerate and adapt to novel salinity regimes remain poorly resolved. Here, we investigated how populations of the calanoid copepod *Acartia tonsa*, a marine zooplankter with broad salinity tolerance, persist and locally adapt across the steep salinity gradient of the North and Baltic Seas.

We used a common-garden design combined with whole genome sequencing (WGS) to test for local adaptation of copepods collected from 14 locations spanning a salinity gradient from marine in the North Sea to near freshwater conditions in the northern Baltic Sea. We quantified survival and metabolic rates under low-salinity stress and analyzed gene expression profiles to identify transcriptomic mechanisms driving salinity tolerance.

There was clear genetic differentiation between North and Baltic Sea populations,

with evidence of additional structure within the Baltic. Physiological and transcriptomic data support this pattern: Baltic copepods showed a higher capacity to survive and tolerate low-salinity stress compared to North Sea animals with a more stringent gene expression response and an osmoregulatory strategy driven by active transport processes. Together, these findings suggest that *A. tonsa* has not only colonized the Baltic Sea successfully, but has also undergone population-specific adaptation to its low salinity conditions.

By integrating genomic, transcriptomic, and physiological data, our study highlights the importance of multi-faceted approaches to uncover the mechanisms of adaptation to environmental stressors. These insights are critical for predicting species' resilience to ongoing climate-driven changes in salinity, particularly in coastal and estuarine systems where shifts are expected to be most pronounced. Here, *A. tonsa* serves as a valuable model organism for understanding evolutionary potential and vulnerability in widespread marine species under pressure from rapid environmental change.

Acute heat stress results in sex-specific mortality in birds

Payne B¹, Amer A¹, Haussmann B¹, McGrath M¹, Pham K¹, Wada H¹, Schwartz T¹

¹Auburn University

POSTER SESSION 1 - **P01.281**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

As temperatures reach unprecedented highs due to global warming, understanding of mechanistic basis for adaptability to heat stress is essential to predict the impact of extreme temperature events on the persistence of animal populations. The overarching goal of this study was to understand the sex-specific effects of acute heat stress on physiological blood measures and cellular/molecular damage. Zebra Finches (*Taeniopygia guttata castanotis*), desert-adapted Australian birds, provide an ecologically relevant study system. Stress resistance has been suggested to be sex-biased with possible links to homogamety/heterogamety of the sex chromosomes and differential hormone expression. As the heterogametic sex, we hypothesized that females (ZW) would be more susceptible to damage from heat stress than males (ZZ).

We conducted an acute heat stress experiment using zebra finches bred at Auburn University, that were all adults under one-year-old. Male and female birds were assigned to two groups: Control, maintained at 22.5°C, and Acute Heat, exposed to 43°C for 5 hours. Baseline blood samples were taken two weeks prior to treatment and blood/tissues were collected immediately after treatment. Fresh whole blood was used for hematocrit, glucose, and ketone measures. DNA from blood cells was used to quantify telomeres and mtDNA copy number by quantitative real-time PCR. Telomeres are known biomarkers of acute and chronic stressors, having demonstrated to be predictors of longevity in the species. Mitochondrial DNA copy number is predictive of metabolic capacity and autophagy in response to mitochondrial damage. Specifically, we predicted that telomere lengths would be shorter and mtDNA copy number lower in females prior to heat exposure if they are more vulnerable to the stressor.

Despite the treatment of 43°C for 5 hours reported to be non-lethal in the literature, in this experiment we observed 12.5% mortality (11 birds) from this acute heat stress treatment. Only female birds died. Upon closer inspection of the data, we observed that all but one of the birds that died were from a “younger” cohort of adults (4-6 months old), relative to a slightly older cohort of adults (9-11 months old). We generated model-predicted probabilities for mortality and found both sex and age-category to be significant predictors (P-value < 0.05), with young females having 22.2% predictive probability of mortality and older females only 4.3%, while males of both age categories have near zero predictive probability of mortality. To test if molecular biomarkers taken at baseline were predictive of mortality due to acute heat, we compared young heat stressed females that did and did not die. Preliminary analysis suggests none of the baseline molecular biomarkers were predictive of mortality.

Our unexpected mortality results indicate that young adult females are the most susceptible group of young adults to heat stress, which could have important consequences on future recruitment into the population under climate change scenarios. This finding emphasizes the importance of studying the effects of stress across sexes and age classes to understand the impact of extreme heat events on population viability. However, this was a lab experiment on captive reared birds. Further research is needed to determine if these results are replicable in lab and field populations. Additional research is underway in our group to examine how males and females differed in cellular damage and repair processes that may contribute to the sex-biased mortality. This research brings new insight to sex-biased response to heat stress in birds.

Adaptive and non-adaptive responses to metal contaminants and pathogens in wild brown trout *Salmo trutta*

Cote J¹, Gauthier L, Jean S, Blanchet S, Loot G, Hannsson S, Jacquin L

¹Crbe Laboratory

POSTER SESSION 1 - **P01.257**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Multiple stressors are leading to major changes in rivers. Among them, the interaction between chronic pollution and emerging pathogens remains poorly known. Moreover, we do not know whether wild fish populations could show adaptive divergence in response to this combination of stressors. In a collaborative project, we investigated the evolutionary responses of wild brown trout *Salmo trutta* to combined metal contamination and/or exposure to the emerging pathogen *Tetracapsuloides bryosalmonae* responsible for the highly lethal PKD disease (Proliferative kidney disease) in Europe. We sampled 40 fish populations along gradients of metal pollution from historic mining and parasitism risk (variations of parasite prevalence and load). Using 192 SNPs, we compared the genetic diversity and genomic structure and measured fish phenotypic traits such as morphology,

coloration, body condition, and immunity indicators to measure their genetic and phenotypic divergence and health status. Results show a phenotypic divergence on several traits linked to variations in metal contamination (especially by Pb, Cd and Cu). due to mining, even centuries after the closing of the mines. To investigate the evolutionary mechanisms leading to such divergence, we then used a Pst-Fst approach, suggesting that multiple stressors could be a selective driver of phenotypic divergence in mountainous rivers. We also used a GEA analysis (Genome-Environment association) to characterize main SNPs involved in response to pollutants (preliminary results). With this study, we hope to encourage future studies in the growing field of evolutionary ecotoxicology, to better forecast the consequences of global change and multiple stressors on the evolutionary trajectories of wildlife.

An evolutionary and mechanistic study of stressor interaction patterns between pesticides, fish predation and heatwaves in natural populations of *Daphnia magna*

POSTER SESSION 1 - P01.258, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Because of global change, species are increasingly facing a multiple-stressor world. This is especially concerning as global change stressors may magnify each other's negative effects. Notably, such stressor interactions cannot easily be predicted by the effect of single stressors, highlighting the crucial need for explicit multiple-stressor research to avoid so-called ecological surprises. Several knowledge gaps remain to advance multiple-stressor research and to transform it into a more predictive discipline, which is crucial to integrate it into risk assessment frameworks. Therefore, I will fill these knowledge gaps by investigating how natural populations of *Daphnia magna* respond to pesticide pollution, fish predation, and heat waves. Firstly, I will research the evolution of natural population tolerance to pesticides, fish predation and their interacting response patterns through common-garden exposure experiments and

explore how natural populations of *Daphnia magna* are adapted to alternating between combined and single stressors through ecotoxicological experiments. Secondly, I look for 'super clones': I expose clones with strong 'pesticide and fish' resistance to heatwaves, to obtain natural populations that are resistant to a wide range of stressors. Meanwhile, I focus on the transcriptome's role in shaping tolerance in *Daphnia magna*. I will be sequencing RNA to explore the types of interactions at the gene level and the regulation of biological pathways for natural population fitness in *Daphnia magna*. This research will contribute to our understanding of patterns of stressor interactions and the evolution of adaptations in natural populations.

KEYWORDS: Evolution; Adaptability; Multiple stressor; Transcriptome; *Daphnia magna*

Biogeographic and adaptative history of the butterfly *Heliconius erato* in Neotropical forests: understanding the past to preserve the future

Machado P¹, Freitas A¹, Silva-Brandão K²

¹Universidade Estadual de Campinas - UNICAMP, ²Museum of Nature Hamburg, Leibniz Institute for the Analysis of Biodiversity Change – LIB

POSTER SESSION 1 - P01.268, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The evolutionary history of the Neotropical region over the last 250 million years is related to a succession of major geological events that altered changed the continents and ocean basins, as well as the climate and evolution of species. The Brazilian rainforests experienced undergone these events, including the Miocene uplift of mountains, changes in the course of rivers in the Amazon, and the climatic oscillations of the Pleistocene.

These processes, such as the uplift of the mountains, rivers and other geographic barriers, and climate fluctuations, contributed to the great diversity found in the Amazon and Atlantic Forests. On the other hand, the climate changes taking place in the Anthropocene may not be a “generator of diversity” but rather of extinction. The process of evolution is not occurring at the same rate, resulting in a loss of genetic diversity, generating a decrease in the adaptive response of species.

The use of molecular tools has allowed us to better understand how climatic and geological events and changes in the landscape influence the diversification and demographic, evolutionary, and adaptive processes of natural populations. In this work we are using SNPs (single nucleotide polymorphisms) to identify possible neutral and adaptive polymorphisms in populations of the butterfly *Heliconius erato* (Nymphalidae: Heliconiini), a widely distributed Neotropical butterfly, occurring in several

biomes including the Amazon, Atlantic Forest, Cerrado, and Pampa.

We aim to: (i) analyze the structure of the genetic diversity in *H. erato* across its geographic range; (ii) investigate genomic signatures that indicate historical connections between the southern Atlantic Forest and western Amazon, as well as between the northern Atlantic Forest and eastern Amazon; (iii) identify genes associated with local adaptation in response to climatic variation; and (iv) assess how both neutral and adaptive genetic variation may respond to future climate change scenarios. A total of 276 individuals from 47 localities were sampled, representing the most comprehensive sampling to date for investigating the proposed objectives and hypotheses.

Butterflies are organisms considered to be environmental bioindicators, and the presence or absence of certain species in certain areas can be indicative of the state of conservation of an environment. *Heliconius erato* is a widely distributed species, found in different environments, from conserved areas to urban areas. If our results show that this very common species will lose genetic variability, what can be expected of restricted species?

The expected results will contribute to a deeper understanding of the processes that have shaped Neotropical biodiversity and how species may respond to climate change over time.

Bridging developmental plasticity and climate adaptation through evolutionary genomics, population genetics and transcriptomics in African *Bicyclus* butterflies

Seudre O¹, Carruthers M¹, Murkwe M², Fokam É², Oostra V¹

¹Queen Mary University of London, ²University of Buea

POSTER SESSION 1 - P01.291, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The climate crisis endangers much of our world's biota, urging the need for an in-depth understanding of species' adaptive potential. Phenotypic plasticity, the expression of multiple phenotypes from a single genome, is a well-studied adaptation to short-term environmental fluctuations, but its contribution to long-term adaptation remains contentious. In seasonal environments, phenotypic plasticity is often triggered during development, when individuals integrate environmental cues into molecular pathways that will later shape their adult traits. With increased climatic stochasticity, these finely tuned cascades might lead to mismatches between the environment and the expressed phenotype. The risk for wild populations is that new responses cannot evolve rapidly enough, due to insufficient genetic variation in core regulators or due to developmental constraints.

Our research bridges evolutionary developmental biology, population genetics, and conservation genomics to investigate the molecular basis and adaptive potential of seasonal plasticity in *Bicyclus* butterflies, a diverse African genus that exhibits differences in seasonally-driven developmental responses. In some species, such as the lab-adapted *Bicyclus anynana*, seasonal morphs are highly distinct: temperature cues during development determine whether individuals develop into short-lived, reproductive wet-season forms or long-lived, inactive dry-season forms. In other species across the phylogeny, phenotypic plasticity is either reduced or absent. Here, we combine wet-lab developmental experiments with whole-

genome and population genomic approaches in wild *Bicyclus* species to understand how developmental plasticity contributes to climate adaptation. More precisely, we (i) characterise the timing of the developmental window during which environmental cues influence phenotype in *Bicyclus anynana*, demonstrating that phenotypic plasticity is restricted to a narrow period from the late larval stage to early pupation; (ii) apply transcriptomics (RNA-seq) and chromatin accessibility profiling (ATAC-seq) to map the gene regulatory networks that establish alternative seasonal forms in this species; (iii) leverage the diversity of plastic strategies across the *Bicyclus* phylogeny to (a) test how plasticity levels shape intraspecific variation in core developmental regulators, and (b) identify genomic features associated with plasticity, generating 14 high-quality de novo genome assemblies and integrating these with population resequencing data; and (iv) assess how selective pressures on these regulatory elements are driven by ecological gradients using 6 populations in 3 habitats from 3 focal species in Cameroon, to help predict their adaptive potential under climate change.

Together, this research provides an integrated developmental and evolutionary framework for understanding how phenotypic plasticity evolves and supports adaptation in the wild. It generates valuable genomic resources for understudied African butterflies, informs conservation strategies under Anthropocene-driven pressures, and advances broader efforts to uncover the molecular basis of adaptation in biodiversity hotspots.

Cold-response is altered by salinity exposure in an intertidal snail

Inaebnit T², Tiedemann R², Johnson D³, **Dennis A**^{1,2}

¹University Of Namur, ²University of Potsdam, ³Virginia Institute of Marine Science

POSTER SESSION 1 - P01.267, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Melampus is a genus of air breathing estuarine snails that are capable of high dispersal via planktonic larvae. Three cryptic species are found in Spartina dominated marshes on the Atlantic coast of North America, where they have distinct but patchily overlapping ranges. It is not clear what determines the areas of species co-existence, but ecological niche modelling suggests that ocean salinity and temperature differ subtly between their respective geographic ranges. To explore the genetic basis of response to these interacting stressors, we acclimated *Melampus jaumei* to different salinities (5, 20, and 35ppt) followed by an acute cold shock.

We used transcriptomic and metabolomic comparisons in the same individuals to show that salinity exposure markedly changed cold response. This has also helped identify putative genes associated with freeze tolerance through the initiation of ice formation (ice nucleation). Since these snails live in tidal estuaries with strong salinity gradients and highly fluctuating conditions, this suggests that subtle differences in their response to interacting stressors could explain large scale geographic variation among species. It also highlights the importance of preserving entire estuarine habitats: the highest intertidal zones occupied by these species are frequently eliminated by sea wall construction, which will effectively reduce both species diversity and the physiological variation that accompanies this.

Conservation genomics of the threatened boreal wood-decay fungus *Amylocystis lapponica*

POSTER SESSION 1 - P01.293, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Old-growth forests are declining due to intensive forestry activities. This has significantly reduced the availability of dead wood substrates that are essential for the survival of many saproxylic organisms. Wood decay fungi are the main decomposers of dead wood and play a pivotal role in the carbon cycle and nutrient cycling in boreal forests. They rely on a continuous supply of suitable dead wood that they can colonize, decompose, and eventually leave once the resources are depleted. *Amylocystis lapponica* is a red-listed, wood-decaying polypore fungus with a strong affinity for undisturbed, late-successional forests. It likely expanded its range across northern and eastern Europe following the postglacial colonization of its main host, *Picea abies*. In this study, we investigate the genetic structure and levels of genetic variation in *Amylocystis lapponica* across populations in northern Europe, focusing on how forestry practices may have influenced these patterns. To address this, we assembled a broad collection of *A. lapponica* isolates and conducted population genomic analyses based on SNP data.

Materials and methods: A total of 48 fruit bodies of *Amylocystis lapponica* were collected from old-growth forests in six Northern European countries: Slovakia, Russia, Poland, Sweden, Finland, and Norway. DNA was extracted and SNP data were generated to study genetic variation. We analyzed population structure using both admixture modeling and principal component analysis, and tested for isolation by distance by comparing genetic and geographic distances between populations. Genetic diversity within

populations was measured using standard statistics, and signs of historical population expansion or contraction were assessed using Tajima's D. Lastly, we examined potential signals of local adaptation to environmental and habitat variables using redundancy analysis (RDA) and association testing with *Samβada*, and related genetic patterns to forest characteristics such as habitat size, isolation, and forest management history.

Results: Our results suggest that *Amylocystis lapponica* likely represents a single panmictic lineage across its Northern European range, in line with expectations of a postglacial expansion from a single refugium. The lack of population structure also indicates that habitat fragmentation reduced population size resulting from human activities has not been strong enough to result in genetic structuring. Further demographic analyses are ongoing to assess whether there has been an overall reduction in population size.

RDA identified several loci potentially associated with climate variation across the study area. This suggests that climate may exert selective pressure on *A. lapponica*, leading to evolutionary differences in allele frequencies along environmental gradients. Functional annotation and further investigation of the adaptive significance of these loci are currently underway.

Conclusion: *Amylocystis lapponica* likely forms a single panmictic lineage across Northern Europe, consistent with postglacial expansion. Climate-driven selective pressures may influence genetic variation, with ongoing research exploring the adaptive significance of the identified loci.

Convergent molecular evolution of thermal tolerance in mammals

¹School of Life Sciences, Faculty of Medicine and Health Sciences, University Of Nottingham, ²Discovery and Translational Sciences Department, Leeds Institute of Cardiovascular and Metabolic Medicine, Faculty of Medicine and Health, University of Leeds, ³School of Medicine, University of Leeds, ⁴LeedsOmics, University of Leeds

POSTER SESSION 1 - P01.261, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Mammals vary in their ability to tolerate heat stress, a trait of great relevance to fitness in the current context of global climate change. For model mammal species such as mice, pigs and cattle, we have gained some specific insights into molecular responses to heat stress, but broader patterns across the wide diversity of the mammal phylogeny are not known. Right across the mammal phylogeny we observe multiple independent emergences of heat tolerant lineages. We wish to determine whether this convergent trait is underpinned by molecular adaptation.

We have assembled a dataset encompassing 230 mammal species for which we have access to annotated

genomes. These species include pairings of close relatives that differ strongly in typical maximum environmental temperatures encountered. For example, we categorise the lion *Panthera leo* as heat adapted as it occupies a geographical range with a typical maximum temperature of 35°C, whereas its paired species, the snow leopard *Panthera onca* (diverging ~9 Million Years Ago) encounters maximum temperatures ~16.5°C. Using branch-site models, we will identify genes with significant variation in selective pressure across these pairings. Comparing results across all convergent instances allows us to identify key genes, pathways and processes common to heat tolerant species.

Disentangling the genomic basis of terrestrialization across animals through a transcriptomics spyglass

Eleftheriadi K¹, Salces-Ortiz J¹, Escudero N¹, Vargas Chavez C¹, Fernández-Álvarez F², Fernandez R¹

¹Institut De Biologia Evolutiva, ²Institut de Ciències del Mar (ICM), CSIC

POSTER SESSION 1 - **P01.250**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Terrestrialization, the colonization of land by aquatic animals, plants, and fungi, is one of the most remarkable events in the history of life on Earth. From a stable marine environment, animals altered respiration, excretion, reproduction, etc. to adapt to life on land. Of the 36 animal phyla, 9 undoubtedly include terrestrial forms. The genomic basis of this transition remains largely unexplored. To uncover the genes that facilitated this adaptation, we subjected terrestrial animals and their aquatic relatives in each phylum to 12 experiments mimicking abiotic stressors associated with land colonization (e.g., visible light and UV exposure, chemosensory cues, and changes in oxygen concentration and osmoregulation). These experiments, involving 23 species from 9 phyla, yielded

~1,000 transcriptomes sequenced using Illumina and PacBio Iso-Seq. We employed comparative transcriptomics, gene co-expression networks and phylostratigraphy to investigate the genomic toolkit underlying terrestrialization, as well as the evolutionary origin of its genetic components. Our results revealed that, while genes involved in responses to abiotic stress in both marine and terrestrial species emerged at similar evolutionary time points, they often belong to different orthogroups, indicating lineage-specific functional diversification. Key lineage- and phylum-specific genes and modules involved in these adaptations were identified. This study provides novel insights into how animals convergently reshaped their genomes to overcome the physiological and morphological challenges of life on land.

Environmental adaptations in *Arabidopsis lyrata*

Steinmann L¹, Novikova P¹

¹Max Planck Institute For Plant Breeding Research

POSTER SESSION 1 - P01.254, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Environmental adaptation in plants involves complex genetic mechanisms that enable survival and reproduction across diverse habitats. Understanding these mechanisms is crucial for uncovering how plants adapt to their ecological niche. *Arabidopsis lyrata* has successfully colonized high latitudes, making it an ideal model for studying patterns of environmental adaptation. Its natural range provides a unique opportunity to investigate the genetic basis of adaptation to diverse climatic conditions such as cold temperatures and high UV radiation. Using

genome-wide association studies (GWAS), we analyzed diploid populations of *A. lyrata* to identify loci associated with latitudinal variation. Our analysis highlights genes linked to critical traits, including flowering time regulation, photosynthesis and soil adaptation, which may be adaptive at high latitudes. These findings reveal key genetic loci that contribute to environmental adaptation in *A. lyrata*. Moreover, our results suggest *A. lyrata* as a promising model for further GWAS studies.

Environmental insights into sex chromosome evolution in a sex-reversing reptile (*Carinacincus ocellatus*)

Ferre Ortega C¹, Saunders P^{1,2}, Wapstra E¹, Burrige C¹

¹University of Tasmania, ²University of Montpellier

POSTER SESSION 1 - **P01.282**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Climate change is threatening many species with extinction, and clear examples are provided by those whose sex is determined by temperature, which may experience future sex ratio biases that threaten population persistence. Species in which sex is determined genetically—by sex chromosomes—were thought immune to these problems. However, examples are accumulating of temperatures overriding genetic sex determination, generating so-called ‘sex-reversed’ individuals.

The viviparous Tasmanian spotted snow skink, *Carinascincus ocellatus*, provides one such example. In this species, climate-induced selection may also be evidenced by geographic variation in the frequency of sex reversal. Concomitantly, the magnitude of sex chromosome differentiation appears higher where sex reversal is rare, as would be expected with increasing genotypic-phenotypic sex mismatch reducing individual fitness. However, the possible selective links between climate, sex reversal, and sex chromosome differentiation has only been established based on observations

from two *C. ocellatus* populations. Here we tested more broadly whether sex chromosome differentiation is greater in colder and less variable climates (i.e., higher elevations), where observations and theory for *C. ocellatus* suggest sex reversal is less likely. We obtained genetic samples from 251 individuals across nine populations spanning the species' altitudinal range and using DArT-seq, a genome complexity reduction-based sequencing technology, we characterized the number and distribution of sex-linked loci across populations.

Our results are not consistent with an increase in sex chromosome differentiation with elevation, and hence climate. This could reflect the possibility that selection against sex reversal has not yet manifest via sex chromosome differentiation at the additional cold climate sites we analysed herein, reflecting localised emergence at one high elevation site and/or genetic isolation among such sites. Future research should quantify rates of sex reversal in additional cold (and warm) climate populations to confirm that our assumptions of sex.

Evolution of facultative symbiosis in the stony coral *Oculina*

Grau-Bové X¹, Levy S^{1,2}, Kim I¹, Najle S¹, Książopolska E¹, Elek A¹, Montgomery S¹, Montes L^{1,3}, Mass T^{1,4}, Sebé-Pedrós A^{1,3,5,6}

¹Centre de Regulació Genòmica, ²Department of Biology and Environment, University of Haifa – Oranim,

³Universitat Pompeu Fabra, ⁴Department of Marine Biology, University of Haifa, ⁵ICREA, ⁶Tree of Life Program, Wellcome Sanger Institute

POSTER SESSION 1 - P01.286, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: Most stony corals are obligate symbionts, dependent on nutrients provided by the photosynthetic activity of dinoflagellates residing within specialized cells. Disruption of this symbiotic consortium leads to coral bleaching and, ultimately, mortality. However, a few coral species exhibit facultative symbiosis, allowing them to survive extended periods of bleaching. Despite this resilience, the underlying biological mechanisms remain poorly understood. Here, we investigate the genomic and cellular basis of facultative symbiosis in *Oculina patagonica*, a thermotolerant Mediterranean coral.

Methods: We have sequenced and annotated a chromosome-scale genome of *Oculina patagonica* and built single-cell transcriptomic atlases for this species—including symbiotic

and aposymbiotic specimens—and two obligate symbiotic corals.

Results and conclusions: Comparative genomic analysis revealed karyotypic and syntenic conservation across all scleractinians, with species-specific gene expansions primarily driven by tandem duplications. Single-cell transcriptomic profiling of symbiotic and naturally aposymbiotic wild specimens identified an increase in phagocytic immune cells and a metabolic shift in gastrodermal gene expression from growth-related functions to quiescent, epithelial-like states. Cross-species comparison of host cells uncovered *Oculina*-specific metabolic and signalling adaptations indicative of an opportunistic, dual-feeding strategy that decouples survival from symbiotic state.

Evolutionary Tuning: Understanding the Influence of Stage-Specific Diet in Shaping Developmental time in *Drosophila melanogaster*

Mohankumar C¹

¹Ashoka University

POSTER SESSION 1 - **P01.255**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Organismal development is influenced by both genetic and environmental factors, with nutrition playing a pivotal role in shaping growth, physiology, and reproduction. Adequate nutrition during development is essential for optimal growth, physiological development, and cognitive function. Conversely, poor nutrition during development can slow or arrest growth, impair physiological function, and ultimately reduce fitness. Studies indicate that adaptation to poor nutrition during development can lead to accelerated development, impacting body size and fertility. However, an organism's life cycle is not defined solely by developmental stage; it also involves critical reproductive stages. Nutritional requirements during these two stages can differ based on their physiological demands. During the developmental stage, nutrients support the growth and development of organs, while in the reproductive stage they facilitate reproduction and survival. This stage-specific allocation of nutrients plays a crucial role in energy investment, shaping an organism's fitness and its evolutionary success. While adaptation to developmental nutrition is well established in affecting organismal development, relatively less is known about how nutritional adaptation during both developmental and reproductive stages can cross-talk over evolutionary timescales to drive pre-adult development and their fitness costs. To address this gap, I used a large outbred population of *Drosophila melanogaster* due to its distinct developmental (larval) and reproductive (adult) stages, conserved nutrition-

responsive pathways, and short generation time, facilitating evolutionary studies. Recent research on nutrition suggests that not just calories but macronutrient ratios modulate health in several model organisms, including *Drosophila*. Hence, I am using isocaloric macronutrient diets for both larval and adult stages. The treatments consisted of two isocaloric diets with varying protein-to-carbohydrate ratios: a carbohydrate-rich (C) and a protein-rich (P) diet for both life stages in a full-factorial design, generating four regimes (PP, PC, CC, CP); the first letter denotes the larval diet, and the second letter denotes the adult diet. To assess the long-term effects of stage-specific dietary effects, I employed experimental evolution for the above regimes, with four independent replicate populations for each. These populations were maintained for 59 generations under selection, followed by two generations of standardization in the ancestral environment (N) to remove the non-genetic effects. Our results show that flies evolved on a carbohydrate-rich larval diet had accelerated development in the ancestral environment compared to those evolved on a protein-rich larval diet. Interestingly, adult diet also influenced pre-adult developmental time, with flies selected on a carbohydrate-rich diet in the adult stage developing slower in the ancestral condition compared to flies on protein-rich adult food. These findings highlight novel insights that selection under both developmental and adult diet influences the pre-adult development in *D. melanogaster*.

Fecal metagenomics as a conservation tool: Assessing pathogen loads in the critically endangered Iberian desman

Sapino Funes R¹, Fernández-González Á², Castresana J¹

¹Institute of Evolutionary Biology (CSIC-UPF), ²Biosfera Consultoría Medioambiental S.L.

POSTER SESSION 1 - P01.256, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Infectious diseases are a major threat to the survival of wild populations, especially in endangered species, where their effects can be amplified by environmental stressors and population fragmentation. Moreover, wildlife is recognized as an important reservoir of zoonotic pathogens that can pose health risks not only to animal populations but also to humans. Recent advances in metagenomic analysis of fecal samples offer a powerful, non-invasive tool to assess the diversity and dynamics of pathogens and parasites that may threaten population viability. However, accurate identification of these infectious agents remains challenging due to the complexity of microbial communities and limited reference genomes. To address these methodological issues, we developed a novel computational framework for detecting potentially pathogenic bacteria from metagenomic sequences. Several key parameters affecting the analysis, including mapping algorithm, database configuration, and alignment-

derived metrics, were optimized to improve identification sensitivity and specificity. Applying this approach to fresh fecal samples from a population of the Iberian desman (*Galemys pyrenaicus*), a critically endangered semi-aquatic mammal, we identified multiple potentially pathogenic bacterial species with varying prevalences within the population. Furthermore, our analysis revealed some desmans with elevated or altered pathogen loads, suggesting variations in environmental exposure, health status, or underlying genomic susceptibility, which opens new research avenues for understanding host-pathogen-environment interactions. From an applied perspective, our study demonstrates a novel approach for species-level pathogen detection using non-invasive fecal metagenomic analysis, providing essential support for population management and the development of more effective conservation strategies.

Gene expansions in herbivorous rodents drive rapid dietary adaptation to climate change

Dearing M¹, Klure D¹, Greenhalgh R³, Shapiro M¹, Orr T²

¹University Of Utah, ²New Mexico State University, ³St. Jude's Children's Research Hospital

POSTER SESSION 1 - **P01.279**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Herbivores routinely feed on plants with bioactive compounds, and in doing so ingest substantial quantities of toxins. How mammalian herbivores have evolved to feed on chemically defended plants and the particular physiological mechanism used is poorly understood. We investigated the evolution of dietary adaptation in mammalian herbivores by focusing on two woodrat species (*Neotoma lepida* and *N. bryanti*) that independently experienced a climate-related event with significant dietary consequences — the extirpation of their primary food resource, juniper (*Juniperus* spp.) and its replacement by creosote bush (*Larrea tridentata*). At the end of the Last Glacial Maximum (~19–15 kya), juniper was extirpated at low elevations of the American Southwest as the region underwent a natural warming event that led to the invasion of creosote bush, a novel species. Juniper and creosote bush produce disparate plant secondary compounds that require different suites of biotransformation enzymes. Creosote leaves are heavily defended by a complex resin of hundreds of chemicals (primarily phenolics, lignans) in substantial quantities comprising 10–25% of its dry mass. We surveyed both species of woodrats across a 900 km transect and combined whole-organism performance assays on

creosote resin feeding capacity, gene induction experiments and population genomics to characterize the genomic architecture and physiological processes that enable these woodrats to feed on creosote bush. We found that creosote-adapted woodrats have greatly elevated gene dosage within multiple biotransformation enzyme families such as P450 cytochrome monooxidases and UDP-glucuronosyltransferases. These duplication events have occurred independently across species and substantially increase expression of biotransformation genes, especially within the glucuronidation pathway. In addition, these parallel expansion events drove copy number of genes involved in one detoxification pathway — the glucuronidation pathway — to substantially high levels. Moreover, copy number variation within key detoxification gene families closely mirrors the historic expansion of creosote bush across the American southwest such that woodrats with longer exposure to creosote bush have higher gene copy number. We propose that duplication resulting in increased gene dosage is an important mechanism by which animals initially adapt to novel environmental pressures.

Genetic Diversity and Population Structure of Bolivian Camelids Revealed by SNP Genotyping

Roman Peña A¹, Strandberg E¹, Johansson A¹, Iñiguez V², Barreta J², Chiri R³, Saavedra V, Gutierrez L³, Periasamy K⁴

¹Swedish University Of Agricultural Sciences, ²University Mayor de San Andres , ³Technical University of Oruro, ⁴International Atomic Energy Agency

POSTER SESSION 1 - **P01.295**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The South American camelids (llamas, alpacas, vicuñas, and guanacos) play a crucial role in Bolivia's economic and cultural landscape and the wider region. These species support the livelihoods of many indigenous communities by providing fiber for textiles, meat, and transportation in high-altitude environments. Understanding their genetic diversity and population structure is essential for effective conservation and management strategies. Previous studies using microsatellites and mitochondrial markers have reported high genetic diversity and introgression in alpacas and population stratification in Bolivian vicuñas. In addition, levels of introgression suggest the need to analyze hybrid individuals between the domestic camelids (llamas and alpacas). In this study, we aimed to evaluate the population structure and genetic diversity within and between camelid species populations in the Bolivian highlands using SNP genotyping data. The study included llamas (N = 177), alpacas (N = 102), vicuñas (N = 103), and hybrids (N = 16). DNA genotyping was performed using the Axiom Camelids Genotyping Array (alpaca) from Affymetrix, containing 59,995 SNPs. After quality control, the final dataset comprised 46,125 SNPs across 370 individuals. Runs of homozygosity (ROH) and principal component analysis (PCA) were conducted using PLINK v1.9. Admixture analysis was performed with the LEA package in R, applying a Bayesian-based model and

testing K values (number of latent factors) from 1 to 10. The results indicated that hybrids and alpacas exhibited significantly higher heterozygosity ($p < 0.05$), as evidenced by lower FROH values (means = 0.09 and 0.10, respectively), compared to llamas (mean = 0.17) and vicuñas (mean = 0.18). These findings suggest greater genetic diversity in alpacas, consistent with the admixture analysis results. The PCA revealed that the first principal component explained 31.5% of the genetic variation among species. Evidence of introgression between domestic species was supported by six hybrids clustering with either llamas or alpacas and three llamas clustering with alpacas or hybrids. Bayesian clustering across all species indicated an optimal $K = 2$, showing admixture in alpacas and hybrids between llamas and vicuñas. Within-species PCA for alpacas and llamas showed slight stratification, with two principal components explaining less than 5% of the variation. For vicuñas, PCA and admixture analysis revealed clear stratification associated with geographic distribution, with more pronounced clustering between the two subspecies than previously expected. The admixture results highlighted a strong geographic structure in vicuñas, in contrast to the domestic species, and the elevated FROH values support limited gene flow and may reflect a historical population bottleneck.

Genomic analysis reveals local adaptation and vulnerability to climate change of the African orphan crop finger millet (*Eleusine coracana*)

Veltman M¹, Thuillet A, Barnaud A, Vigouroux Y

¹Institut De Recherche Pour Le Développement

POSTER SESSION 1 - P01.292, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

An important crop in arid and semi-arid regions, finger millet is valued for its nutritional composition, offering high concentrations of fibers and micronutrients, and its climate resilience, exhibiting improved biotic and abiotic stress tolerance compared to major crops. These properties have earned finger millet the reputation of a climate-smart "super food" that promises to combat food insecurity in parts of the world that suffer from malnutrition and reduced yields due to the effects of climate change. Despite this great potential, evolutionary studies investigating the genetic basis of climate adaptation in finger millet have not been carried out to date. Here we aim to fill this gap by providing a reference panel of more than 200 finger millet accessions sampled across its cultivation range in Africa and India. By analysing genome-wide

patterns of diversity and environmental selection, we identify signatures of local adaptation and their likely environmental drivers. Using predictions of future climatic conditions based on different emissions scenarios and climate models, we map the possible consequences of climate change for genome-environment associations that evolved over millennia, and identify areas where maladaptation to the environment may occur as a result. Finally, we leverage the range of diversity and adaptive potential present in this reference panel to identify candidates for assisted migration into (and out of) areas that are especially vulnerable to climate change. This could not only mitigate potential yield losses and reductions in cultivation area, but also safeguard the precious genetic resources of this underutilised crop for future use.

Genomic signatures and demographic history of the widespread and critically endangered yellow-breasted bunting

Chen G¹, Sin S¹

¹School of Biological Sciences, The University of Hong Kong

POSTER SESSION 1 - **P01.259**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Population declines may have long-term genetic consequences, including genetic erosion and inbreeding depression, which could affect species' evolutionary potential and increase their risk of extinction. Small populations are more vulnerable to genetic threats than common species, but even species with large populations can also be at risk of extinction. The yellow-breasted bunting (*Emberiza aureola*) is a common and widespread songbird in the northern Palearctic regions, but its global population size has drastically declined by around 90% throughout the past 30 years, leading to an upgrade of its conservation status to critically endangered in the IUCN Red List. In this study, we identified three populations within this species using whole-genome resequencing data, but the genetic differentiation between populations was shallow. These populations underwent similar population fluctuations but differed

in the extent of population decline, resulting in lower genetic diversity and more homozygous deleterious mutations in a population comprising individuals on islands. The ancient demographic history was mainly associated with the climate, while population declines over the past 100 generations are likely due to human activities. Our results suggest that the yellow-breasted bunting population before the recent collapse faced relatively low genetic threats and had high evolutionary potential. However, we should be vigilant about the genetic threats faced by this species, as our sampling time occurred at the onset of its recent global population collapse. This study provides valuable genetic information for the conservation of yellow-breasted bunting and also highlights the similar genetic threats faced by other large populations.

Genomics of Brazilian howler monkeys reveals recent inbreeding and species-specific positive selection

McVay K¹, Figueroa-Ildefonso E¹, Freitas J², Portela L², Guimarães V³, Silveira da Mota L³, Monticelli C⁴, Valsecchi J⁵, Perini F⁶, Pissinatti A⁷, Domingues de Freitas P², Goldberg A¹

⁷Primate Center of Rio de Janeiro

POSTER SESSION 1 - P01.275, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Howler monkeys (genus *Alouatta*) are an understudied neotropical primate with a broad geographic distribution across Central and South America, and a wide radiation including between 9-14 species. In parts of their range, particularly in the Atlantic Forest of Brazil, rising deforestation and human encroachment into forests threaten these vulnerable species and increase human-primate interactions. Further, howler monkeys serve as primary reservoirs for multiple zoonotic malaria parasites and are highly susceptible to sylvatic yellow fever. We conducted whole-genome sequencing of 88 howler monkeys (average coverage ~11X) to reconstruct the evolutionary history of multiple howler monkey groups from across Brazil. Genomic evidence of population structure – based on PCA, ADMIXTURE, and *Fst* analyses – suggests different classifications for four major species groups, contrary to current IUCN taxonomic standards, and shows allopatric speciation increases towards the mouth of major Amazonian rivers in concordance with the

Riverine Barrier Hypothesis. We find regional differences in demography, including an increased proportion of long ROH and decreasing population size estimates, which suggest recent inbreeding in Atlantic Forest howler monkeys, potentially resulting from the increased habitat fragmentation in the Atlantic Forest compared to the Amazon rainforest. Finally, we compared signatures of positive selection using G1 statistics; in contrast to most primate studies representing a single species per genus, we tested for shared and unique adaptive histories within a genus. We found enrichment for genes relating to immune response and howler monkey-specific phenotypes like trichromatic vision and folivory, though the genomic regions were species-specific. This evidence for host adaptation to local pathogens aligns with the known burden of infectious disease, particularly in the Atlantic Forest, and is concordant with recent independent histories of the species in different environments.

Homology-Based Mapping of microRNA Evolution Across Mammals

Power S¹, Huang Z¹

¹University College Dublin

POSTER SESSION 1 - P01.288, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The evolutionary history of mammals reflects a continuous process of genetic innovation that has produced remarkable biological diversity. While much effort has focused on understanding the evolution of protein-coding genes, these regions tend to be highly conserved across mammals, which does not fully explain the extent of phenotypic variation observed. This suggests that regulatory elements, particularly non-coding sequences, may play a more significant role in driving evolutionary change.

MicroRNAs (miRNAs) are short non-coding RNAs that regulate gene expression post-transcriptionally. Although there is substantial evidence to implicate microRNAs in organismal complexity, their biological relevance in mammalian evolution remains largely unclear due to limited annotation outside a few model species. Current miRNA prediction methods are heavily dependent on RNA-seq data, which is inconsistently available across mammalian taxa.

Materials and Methods: To address these limitations, this study developed a mapping-based approach to identify miRNA genes using homology, and explore their evolution across mammals. Using a curated set of known miRNA sequences as reference, orthologues were identified across 73 mammalian genomes. Candidate miRNAs were validated through a combination of synteny analysis and secondary structure assessment, and patterns of copy number

variation and gene family gain and loss were analysed in a phylogenetic framework. This homology-based method was then benchmarked against other currently used miRNA prediction pipelines.

Results: Using this approach, 3,519 orthologous miRNA families were identified across a broad range of mammalian genomes. Notably, 3,491 of these families were detected in species where they had not been previously annotated, demonstrating the method's capacity to expand miRNA repertoires in understudied species. Preliminary analysis suggests that patterns of copy number variation and gene family gain and loss may offer valuable insights into the evolutionary dynamics of miRNAs across mammals. When benchmarked against other commonly used annotation methods, this approach consistently identified more miRNA families across genomes.

Conclusions: Leveraging homology to identify miRNAs offers a powerful alternative to RNA-seq-dependent miRNA annotation and enables us to explore the complex evolutionary dynamics of these genes. These findings substantially expand the known miRNA repertoire in mammals and provide a rich resource for downstream evolutionary and functional studies. Overall, this work highlights the importance of studying non-coding regions to better understand genome evolution and its contribution to organismal complexity.

How does inbreeding affect local adaptation in the mountain plant *Arabis alpina*?

Way F¹, Duffy C¹, Lohse K¹, Lustenhouwer N², Hartfield M¹

¹Institute of Ecology and Evolution, University of Edinburgh, ²School of Biological Sciences, University of Aberdeen

POSTER SESSION 1 - P01.265, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The process of adaptation to the environment is impacted by many factors, one of which is the species' mating system. Self-fertilisation is a mating system occurring in 42% of angiosperms including rare species and crops. On one hand selfing causes extreme inbreeding and reduces the efficacy of selection, however theory also indicates that it may increase the fixation of recessive beneficial mutations and promote local adaptation by limiting pollinator-mediated gene flow. To better understand how inbreeding affects adaptation in nature, this project uses the wild mountain plant *Arabis*

alpina to test how intraspecific variation in the mating system has affected environmental adaptation. We have generated whole genome sequence and phenotypic data from replicate high and low elevation populations that are either self-compatible or self-incompatible. We will combine our new dataset with existing data and compare genomic signals of local adaptation to elevation between regions with different selfing rates. These data will help us understand how selfers differ from outcrossers in their response and resilience to environmental changes.

Mitochondrial Insights into the Unique Evolutionary History of Eastern Baltic Cod

Endo Kokubun E¹, Reusch T¹, Han K¹

¹Marine Evolutionary Ecology, GEOMAR Helmholtz Centre for Ocean Research

POSTER SESSION 1 - **P01.276**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The characteristic salinity and oxygen conditions of the Baltic sea have driven local adaptation processes in the Eastern Baltic cod (EBC), particularly in traits related to egg buoyancy and survival. Consequently, divergent selection on reproductive traits has emerged as a barrier to gene flow - even between EBC and the closely related Western Baltic cod (WBC). While divergences in the nuclear genome have been documented, it remains unclear whether similar patterns are mirrored in the mitochondrial genome. Mitochondrial DNA (mtDNA), due to its maternal inheritance, is a suitable marker for tracing the structure of female lineages in this population, where egg survival is linked to older, larger females. Additionally, given that mtDNA in Baltic cod is under neutral evolution, it offers high resolution insights into demographic history. Thus, this study aimed to assess whether local adaptation to the Baltic Sea was accompanied by the presence of one or a few dominant mitochondrial lineages, or whether it occurred within a background of multiple coexisting lineages. We analyzed 115 complete mitochondrial genomes from adult EBC individuals, alongside

comparative sequences from WBC and North Sea cod (NSC). Based on SNP data, we evaluated genetic diversity, population structure, demographic history, and haplotype relationships. EBC showed high genetic diversity, albeit slightly lower than NSC, yet encompassing nearly the full haplotypic diversity of the neighboring populations. Haplotype network revealed centrally placed NSC haplotypes with no shared nodes between NSC and Baltic individuals, suggesting a shared ancestry but no recent genetic exchange. The Baltic cod population originated around 10,000 years ago, during the postglacial expansion of the Atlantic cod into the newly forming Baltic Sea. These findings indicate that EBC harbors a historical mitochondrial diversity shaped by early colonization events, with few mutational changes since then. This suggests that the divergence seen in the nuclear genome observed nowadays is layered upon a much older maternal lineage structure. In this context, EBC is not only a product of recent local adaptation but also an important reservoir of deep evolutionary history, contributing uniquely to the overall genetic diversity of north Atlantic cod.

Narrow admixture zone between populations of the fungus *Trichaptum abietinum* in Norway

Andersen A¹, Lu D¹, Hopland Methlie I¹, Helleland K¹, Myhre Ekeberg I¹, Kauserud H¹, Skrede I¹

¹University of Oslo

POSTER SESSION 1 - **P01.294**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Glaciation cycles have shaped the genetic structure of species we see today. During glaciation species were pushed back into glacial refugia due to colder climate and ice sheet expansion. After glaciation, diverged populations could expand from refugia and come into secondary contact. Plants and animals in Europe show a common pattern in glacial refugia and postglacial migration, but it is unclear whether fungi follow the same pattern.

Trichaptum abietinum, also known as the purplepore bracket fungus, is a common white rot fungus growing on dead conifer wood. In Norway it grows on *Picea abies* and *Pinus sylvestris*. Recently two genetic groups of *T. abietinum* were discovered in Norway, the Atlantic group in western Norway and the Boreal group in eastern Norway. The two groups were suggested to result from two separate migration routes after the last glaciation. In the initial analysis, no admixed individuals were found. In Norway there are

strong climate gradients from west to east. Common garden experiments have indicated that local adaptation to climate may shape the current distribution of these populations.

We ask whether we will find an admixture zone in Norway when including a broader sample and if local adaptation to climate can be identified in the genomes.

We collected 40 samples throughout southern Norway, following the strong climate gradients. Full genome sequencing and population genomics tools have been used to investigate the research questions. We found an admixture zone in the innermost fjords west of the mountains. The admixture zone was confirmed with linkage disequilibrium decay and local ancestry analyses. Redundancy analysis and sliding window analysis of differentiation were also used to screen for candidate loci involved in local adaptation.

Of resilience, population growth, and genetic diversity

Scotti I¹, Boivin T¹

¹Inrae

POSTER SESSION 1 - P01.298, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

We have developed a simple model that combines population growth, genetic diversity, and resilience to disturbances.

By introducing heritable variability in growth rates and sensitivity to disturbances, we show that genetic diversity interacts non linearly with the frequency of disturbances, pushing the population away from the equilibrium frequencies that can be predicted based on theoretical differences in fitness among genotypes.

Depending on the genetic covariance of survival and growth traits and on their genetic architecture, the interactions between disturbance frequency and genetic diversity generate varying long-term population growth rates.

This theoretical model shows that population resilience can be interpreted as a genetic property of populations and that disturbances can maintain genetic diversity in non-equilibrium systems, somehow recalling the intermediate disturbance hypothesis (IDH), applied at the genetic-diversity level.

We finally posit that the parameters of the model can be validated using field data to measure genotype-level growth and mortality traits. This will further allow us to predict the long-term fate of genetic diversity and resilience under climate change.

The model is generic, can be made arbitrarily complex, and can be applied to any biological system.

Phylogeographic and genomic insights unveil the evolutionary history and post-glacial recolonization routes of the Palmate Newt (*Lissotriton helveticus*) into Europe

Carranza B^{1,2}, López-Caro J^{2,3}, Jordà A^{2,3}, Spilani L^{2,4}, Talavera A², Mochales G², Cabana M⁵, Montori A³, Crochet P⁶, Recuero E⁷, García-París M⁷, Martínez-Solano Í⁷, Fernández-Guiberteau D³, Carranza S¹

POSTER SESSION 1 - P01.273, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Quaternary glacial cycles have been key drivers of diversification for Holarctic species, promoting divergence, isolation, and extinction processes in numerous taxa. These cycles facilitated evolutionary radiations in some groups but also erased much of the evolutionary history of species with northern origins. Here, we investigate the evolutionary and phylogeographic history of the Palmate Newt (*Lissotriton helveticus*), a widespread species in post-glacial ecosystems in Western Europe. We generate genome-wide ddRADseq for 205 individuals from 51 populations across the species range and reconstruct its phylogeographic and demographic history, assess population structure, and characterize ecological paleo-niches for the species at different climatic periods. Results identify several distinct lineages exhibiting strong genetic differentiation, primarily driven by geographic barriers and isolation in historical

refugia with admixture in transition zones. Phylogeographic reconstructions suggest that the main glacial refugium for *L. helveticus* was most likely located in northern Iberia. Two main dispersal routes were identified: one extending eastward through the Ebro River Basin and, a second, following a north-eastward pathway across the Pyrenees and into Europe. We specifically pinpoint the origin of Europe's recolonization route to a specific set of localities surrounding Andorra, where *L. helveticus* probably expanded along tributaries to the Garonne River into southern and western France over warm periods. By integrating genomic, geographic, and paleoclimatic data, this study provides an in-depth understanding of how climate shaped the evolutionary history of this temperate species and reinforces the importance of waterways for amphibian dispersal dynamics.

'Plasticity of mutation rates and spectra in the green algae *Ostreococcus tauri* - Effects of temperature and salinity'

POSTER SESSION 1 - **P01.274**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Phytoplankton forms an essential group of organisms, responsible for an estimated 50% of primary production with a major role in aquatic trophic networks and biogeochemical cycles. As oceans are changing rapidly, phytoplankton populations face intense selective pressures. To understand how these species will adapt to these changes, we must first understand how environmental conditions themselves influence genome evolution.

The ultimate source of genetic diversity upon which selection and genetic drift can act is formed by spontaneous mutations, which opens the door to evolution. Thus, the spontaneous mutation rate (μ), that is, the number of de novo mutations per generation per nucleotide, defines the adaptive potential of a species or population. Traditionally, μ is often treated as species-specific and stable; however, with advances in sequencing technology it has become clear that the environment has a major influence on μ .

We evaluated the plasticity of μ in *Ostreococcus tauri*, a marine picoeukaryote and model phytoplankton species. We performed mutation accumulation (MA) experiments under 4 different environmental conditions: high temperature (26°C), low

temperature (14°C), high salinity (50 g/L) and low salinity (20 g/L).

Short-read sequencing revealed that the base substitution rate (μ BS) doubled under high salinity and low temperature, and increased four-fold under high temperature compared to standard conditions. In addition, we sequenced a subset of MA lines with long-read PacBio and/or Nanopore sequencing to find structural mutations (SM) and estimate μ SM under the different conditions. This last technique also allows us to look at DNA methylation in the and make a correlation with changes in μ , taking another angle at the influence of epigenetic mechanisms on species adaptation. Finally, we use RNA-seq data allowed us to assess the influence of transcription on local mutation rates.

These results demonstrate that μ is highly plastic and changes with water temperature and salinity, 2 parameters that are expected to evolve significantly with global warming. This quantification of μ plasticity will be of service for studies on population dynamics and genetic diversity of phytoplankton species, helping to understand the influence of the environment on genetic diversity, which in itself is essential for resilience of populations against environmental changes.

Predicting adaptive potential from genomic data and its implications for conservation

Abson K¹, Zijmers L², Mittell E¹, Eyre-Walker A², Hadfield J¹

¹University of Edinburgh, ²University of Sussex

POSTER SESSION 1 - P01.260, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Adaptive potential, the capacity of a population to adapt, is essential to avoid extinction in a rapidly changing world. Therefore, accurately measuring a population's adaptive potential is crucial for informing effective conservation strategies. Molecular genetic diversity is an attractive and frequently used proxy of adaptive potential. However, previous research has cast doubt on the suitability of traditional molecular markers (allozymes and microsatellites) for predicting adaptive potential. In recent years, advances in

sequencing technology have instead shifted focus towards measuring nucleotide diversity and variation in functional regions. But the predictive power of these now favoured genetic measures is yet to be determined. Using literature-derived estimates from >80 species, we quantify the relationship between nucleotide diversity and the mean additive genetic variance of traits in a population– a theoretically well-motivated proxy for adaptive potential– to re-evaluate the usefulness of current genetic measures in a conservation context.

Predicting the genomic offset of fruit trees to climate change by building a reproducible bioinformatic pipeline

Criado M¹, Brisson M¹, Chen X¹, Venon A¹, Hansart A¹, Bourgeois Y³, Olivier F², Marchadier E¹, Cornille A⁴
¹Université Paris Saclay, INRAE, CNRS, AgroParisTech, GQE –Le Moulon, ²Centre National de la Recherche Scientifique (CNRS), Université Grenoble-Alpes, Grenoble INP, TIMC UMR 5525, ³Institut de Recherche pour le Développement (IRD), ⁴New York University Abu Dhabi

POSTER SESSION 1 - P01.264, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Climate change challenges biodiversity and food security, impacting organisms and ecosystems. Genetic diversity in crops and their wild relatives is vital for climate adaptation, as wild species historically supported crops adjusting to environmental changes. Therefore, investigating phenotypic plasticity and genetic adaptation of crops and their wild relatives is essential, though debates persist about their relative roles under climate change. We investigate the local adaptation and plasticity of four temperate perennial crops and their wild

relatives to climate change and predict their genomic offsets. We start with the apple tree as a model and will extend our analyses to other fruit trees. We present an unprecedented bioinformatic workflow that combines predictive tools, climatic data, and genomic variants that aim to be applied to a wide range of model systems and data. The genomic offset predictions are validated using climate-related fitness estimates recorded in common gardens planted in diverse European orchards.

Repeated local adaptation and genetic vulnerability to climate change in North American songbirds

Ferrer Obiol J¹, Bossu C¹, Carpenter A¹, Winger B², Ruegg K¹

¹Biology Department, Colorado State University, ²Department of Ecology and Evolutionary Biology and Museum of Zoology, University of Michigan

POSTER SESSION 1 - P01.299, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Across the Western Hemisphere, it has been estimated that half of all songbird populations are in decline. These declines are driven in part by disruptions to the genetic adaptations that enable these species to thrive in spatiotemporally heterogeneous environments. We have growing evidence that anthropogenic climate change is decoupling key genotype–environment associations, thereby accelerating population declines and local extinctions. At the Bird Genoscape Project (birdgenoscape.org), we are using next-generation sequencing methods to create maps of genetic variation - 'genoscapes' - across the breeding range of Western Hemisphere songbird species. Genoscapes are harnessed to track breeding populations to their respective wintering grounds, quantifying exposure to threats throughout the annual cycle. As part of this umbrella project, we are leveraging a comprehensive

whole-genome sequencing dataset comprising range-wide data for thousands of individuals in 39 North American bird species. Using this dataset, we aim to: (1) assess the repeatability of adaptation to climate by quantifying within-species associations between allele frequencies and climatic gradients; (2) evaluate how life-history strategies and ecological traits (e.g., migratory behaviour, range size, habitat) influence patterns of local adaptation; and (3) integrate our findings across species to produce comparative vulnerability maps that highlight populations and regions most at risk under future climate scenarios. By combining genomic, ecological, and spatial data, our research will provide novel insights into the genetic architecture of repeated local adaptation to climate in songbirds, and highlight regions and populations of conservation priority.

Selection mirage - Ecological selection led to repeated color changes during plant domestication

Winkler T^{1,2}, Kadner M¹, Graf C¹, Martinez J¹, Singh A¹, Stetter M^{1,2}

¹Institute for Plant Sciences, University Of Cologne, ²Cluster of Excellence on Plant Sciences (CEPLAS)

POSTER SESSION 1 - **P01.272**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Adaptation to environmental shifts often went along with numerous trait changes. This leads to the inference of selection on traits, but the connection between the novel trait variation and improved fitness often remains unknown. During domestication, plants adapted to agroecological environments and human preferences. During the process, a number of traits changed convergently across crop species in response to domestication and species have even been domesticated multiple times independently. Grain amaranth has been domesticated at least three times in different regions of the Americas. While some fitness-relevant domestication traits, including the loss of seed shattering and increased seed size, are not observed, the seed color has changed from dark to pale in all three crop species. The connection between seed color and environmental adaptation shows that selection 'sees' more than the human eye.

We identify the links between metabolic and gene expression networks controlling seed pigmentation through multi-omics. Domestication led to a strong downregulation of color pathway genes and a decline in pigment metabolites, leading to pale seeds. Genome-wide association revealed two major loci controlling seed color, of which one is causal for pale seeds.

The same locus was causal for seed color and germination differences in a mapping population. In an ecological assay, pale seeds were less dormant than dark seeds and their faster germination provided an advantage in agroecological environments without competition. After two years of storage, dark and pale seeds germinated equally fast, highlighting the contrasting adaptations to wild and agroecological environments. A haplotype network of the germination locus showed independent knock-out mutations in the same regulator gene as origin of pale seed color, highlighting the repeated emergence of pale seed color in the three domesticated grain amaranth species.

Pale seed color has emerged across numerous domesticated and wild species in response to human-mediated environmental change. We demonstrate how selection during environmental adaptation dragged along a seemingly fitness-unrelated trait through mediating pleiotropy of the regulator for germination properties. Our work shows that predicting the selective pressures from observed trait changes can be challenging and that interdisciplinary approaches, including ecology and omics are required to understand adaptation to future changes.

Selection pressures across the introgression landscape of Southeast Asian domestic cattle

Aninta S¹, Wang X¹, Nursyifa C¹, Bradshaw C^{2,3}, Al-Chaer A¹, Priyono D⁴, Persada A⁵, Tribudi Y⁶, Sudrajat P⁷, Gaina C⁸, Jiang Y⁹, Lenstra J¹⁰, Cauble-Sims R¹¹, Rosen B¹², Hagen D¹³, Heaton M¹⁴, Smith T¹⁴, Sinding M¹, Solihin D⁵, Agil M⁵, Purwantara B⁵, Heller R¹

POSTER SESSION 1 - P01.280, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Introgression, or the movement of genomic regions between species, is prevalent in nature but its consequences are not well understood. It has been suggested that such interspecies gene flow could help promote adaptation to the local environment. Several domestic livestock breeds in Asia are known to have introgression from wild relatives which assist local adaptation to their environment alongside many other traits desired by humans. In areas of tropical climate, for example, *Bos indicus* is the more prevalent cattle breed as it is more resistant to pathogens and heat, unlike its relative *Bos taurus* that is more adapted to cooler climate in the northern part of the globe. However, it is not clear what controls which genomic regions are able to be introgressed, or why some background genomic variation persists. We used whole genome sequencing data of 90 individuals of admixed cattle from Indonesia (*Bos indicus* x *javanicus*, mean reads depth ~15x) coming from four different local breeds, i.e. Aceh, Pesisir, Pasundan, and Madura, to investigate the factors promoting introgression between species. From a previous study, these admixed Indonesian cattle were found to have experienced large

amounts of introgression from their wild relative, *Bos javanicus*, with differing proportions in different breeds. The abundant *Bos javanicus* ancestry encountered suggests positive selection towards these wild introgression, leaving questions on what impedes the other regions from receiving them and why different breeds have different proportions. To detect whether selection is among the factors shaping the persistence of *Bos indicus* genomic background in the admixed Indonesian cattle, we analysed genomes of these breeds that contain only the *Bos indicus* ancestry. We ran a number of selection scans detection as well as fitting demographic models to pinpoint the forces that shape their genomes. Additionally, we attempted to determine whether the genes appeared as being selected from the general selection scan were selected before or after introgression. We will discuss the forces that shape introgression landscapes in admixed cattle breeds, which will contribute to our more fundamental understanding of the genomic background of species barriers, a central question in the topic of speciation and therefore, the formation of biodiversity.

The Evolution of Plasticity and Heat Adaptation in Green Algae

Harry-Paul Y¹, Ness R¹

¹University Of Toronto

POSTER SESSION 1 - **P01.300**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Climate change significantly threatens biomes and their associated organisms and ecosystems worldwide, affecting species' functions and survival. The increase in temperatures and related environmental changes challenge the physiological limits of many species, potentially altering species' survival and interactions. The speed at which climate change occurs makes it difficult for species to adapt quickly, which can lead to accelerated decline and even extinction. Some species may respond to these changing conditions by relocating to more favourable environments, while others attempt to adapt through genetic changes or phenotypic plasticity. Phenotypic plasticity allows a single genotype to express multiple phenotypes, providing a potential mechanism for organisms to cope with climate change. However, the interplay between genetic changes and phenotypic plasticity is complex, as both contribute to an organism's phenotype and adaptation, and plasticity is often under partial genetic control. Thus, we aim to answer the following questions: How does plasticity influence adaptation to novel environments? Specifically, can long-term evolution evolve a plastic phenotype in response to fluctuating environmental temperature stress? And does plasticity aid or hinder the adaptation to more extreme temperatures? Here, we utilize the unicellular green algae *Chlamydomonas reinhardtii* to determine how organisms evolve and utilize phenotypic plasticity to adjust to temperature changes. The current body of research examines plasticity in response to acute heat exposure rather than long-term heat stress. Therefore, I aim to

understand the role of plasticity in the evolution of long-term heat responses in *C. reinhardtii* to extreme temperature changes. To first understand the extent of the natural variation in heat tolerance in various genetically distinct strains of *C. reinhardtii*, 10 natural strains were sampled from a latitudinal gradient from Quebec, Canada, to Florida, USA. Strains were exposed to temperatures ranging from 16°C to 39°C over four days, where their growth was monitored regularly via spectrophotometry. Despite differences in latitude, *C. reinhardtii* strains displayed similar fitness curves with an optimum growth temperature of 28-32°C and a sharp decrease in fitness after 32°C and ultimately cell death around 39°C.

A fluctuating temperature regime was used to evolve a plastic phenotype. Here, cell lines would fluctuate between the stressful environment of 20°C and 37°C every four to five days. Replicate cultures were grown for 9 months in either the fluctuating regime, a 20°C or a 37°C constant condition, and a 25°C control. Current data reveal that the fluctuating regime performs equally or better than its specialist counterparts, thus demonstrating that a plastic phenotype can adapt to extreme temperature stress via a fluctuating regime.

To understand the genetic regulation and mechanisms behind the evolution of heat tolerance and the plastic changes, cells used in the long-term evolution experiment will be sequenced to identify mutations of interest. Specifically, whether SNPs are shared between the fluctuating and constant growth regimes and if these SNPs foster heat tolerance

The Evolutionary Genomics Of Pesticide Resistance In The Water Flea *Daphnia Magna*

POSTER SESSION 1 - **P01.277**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

How does a changing environment shape the organisms' genome? The interplay between ecology, genetics, and development is a fascinating, yet complex, unanswered question within evolutionary biology. Despite the enormous advancements in molecular and computational methods, evolutionary studies combining genome sequencing and functional assays remain scarce at a landscape level. In the context of my PhD, I am using populations of the water flea (*Daphnia magna*) within an agricultural-vs-non-agricultural pond system in Belgium to study the evolution of their resistance to pesticides. The aim is a complementary approach to study their adaption, merging "traditional" population genetics tools with

state-of-the-art -omics technologies. Here, using 396 newly re-sequenced genomes, I will present the population structure of *D. magna* in this system, as well as the genomic loci that show signals of natural selection to pesticide resistance. By combining these results with gene expression and chromatin accessibility assays in the future, I aim to narrow down the loci that are functionally relevant to the protection against the pesticides, and identify coding and regulatory changes that are under selection. Overall, this study aims to provide a comprehensive insight into evolution in a landscape highly exposed to a prevalent anthropogenic stressor.

Time-Lagged Genetic Erosion from Habitat Fragmentation Undermines Evolutionary Resilience in Arthropods

Bilde T¹, Pedersen J¹, Bechsgaard J¹, Corcoran D¹, Normand S¹

¹Aarhus University, ²University of Exeter, Centre for Ecology & Conservation

POSTER SESSION 1 - **P01.290**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

The intensification of land use over past millennia has dramatically accelerated habitat loss and fragmentation, processes that reduce population sizes and limit gene flow. These demographic shifts can amplify genetic drift, with potentially profound consequences for the evolutionary potential of species. However, empirical data on the population genomic impacts of habitat fragmentation—particularly in ecologically critical but presumed abundant taxa like insects and arthropods—remain limited. Increasing reports of insect and arthropod declines underscore their vulnerability, as many of these species have short generation times and sometimes low dispersal capacity, making them particularly sensitive to land use changes.

To assess how land use change and habitat fragmentation affects genetic composition and demographic trajectories, we combined historical agricultural land-use data from Denmark with whole-genome resequencing of 20–40 populations of each of 20+ arthropod species (beetles, collembola, spiders) from natural grasslands. Our results show that agricultural expansion has decreased habitat suitability, increased population isolation, and coincided with severe declines in effective population sizes. Gene flow estimates also revealed sharp recent reductions aligning with periods of agricultural intensification.

Notably, these changes in population size and connectivity have yet to fully manifest in

observed levels of genetic diversity due to a process known as “drift debt.” Following a population decline, genetic diversity does not immediately vanish; it erodes gradually over generations as a result of genetic drift. This time-lag means that populations may currently appear genetically healthy while still being on a trajectory of ongoing loss, particularly in the absence of gene flow. As a consequence, evolutionary potential is silently diminishing, with reduced capacity for adaptation to ongoing and future environmental stressors such as climate change.

We also perform environmental association studies and analyses of adaptive variation in response to environmental and climatic parameters, to identify how variation in life-history traits interact with environmental change to shape genomic structure and adaptive potential across arthropod species. Our findings highlight the potentially overlooked genetic risks facing even common species in fragmented habitats, and emphasizes the benefits of incorporating genomic analyses into management efforts to identify drivers of genetic erosion. Our study contributes to understanding how land use and environmental pressures shape genomic diversity, with important implications for the resilience and long-term persistence of biodiversity in a rapidly changing world.

Time-structured genomic sampling reveals abrupt and rare genetic shifts in *Eunicella singularis* populations, challenging snapshot connectivity estimates.

POSTER SESSION 1 - P01.284, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Population connectivity (the exchange of individuals between populations) is a key process shaping metapopulation genetic structure, supporting population persistence and local adaptation. Therefore, accurately assessing connectivity is essential for effective ecosystem management, particularly in the context of spatial planning. It is often inferred empirically using genetic data, through approaches based on population genetic identity, genetic differentiation between populations, or the detection of first-generation migrants.

In coastal ecosystems, connectivity is primarily driven by the dispersal of pelagic larvae, and is thus influenced by ocean currents and species-specific life-history traits (e.g., spawning periods, larval duration). Both factors change over time, due to environmental and climatic variability. Yet, empirical connectivity studies typically rely on snapshot datasets, overlooking potential fluctuations through time.

Here, we investigated the robustness of connectivity assessments based on genomic data in a highly variable coastal environment. Using the temperate octocoral *Eunicella singularis* as a model species, we evaluated the temporal stability of population genetic identity, genetic differentiation, and inter-population recruitment patterns using a time-structured genomic dataset that include historical samples (2008–2014) and cohort-specific samples from 2022.

We show that large-scale genetic structure remains predominantly shaped by geography and that the genetic identity of most populations stays stable over time. However, some low-density populations exhibit marked

temporal shifts in genetic identity, likely driven by rare recruitment events involving genetically differentiated individuals. These shifts permanently alter the genetic identity of the affected populations and influence broader patterns of genetic differentiation. Furthermore, we identify rare inter-population migration events by detecting first-generation migrants, events that are unlikely to be captured by snapshot studies. Indeed, methods based on first-generation migrant detection may fail to identify such events if the relevant generation is not sampled, whereas estimates based on population genetic identity or differentiation may detect their consequences, but would not distinguish rare, massive migration events from low, stable migration patterns, thereby obscuring their episodic nature.

Our findings uncover the occurrence of rare, high-intensity connectivity events and emphasize their lasting impact on the genetic identity of *Eunicella singularis* populations, particularly in fragmented or declining populations. Unlike continuous low-level migration, these episodic events can drive abrupt genetic shifts, with profound implications for metapopulation dynamics and evolutionary trajectories. As such, they are likely to be underestimated or mischaracterized by conventional snapshot genetic studies. Recognizing and accounting for these infrequent but consequential events is essential for a more accurate understanding of population connectivity, especially in the context of accelerating population fragmentation and environmental change driven by climate change.

TO HAVE OR NOT TO HAVE: Does Having a Reference Genome Make a Difference?

López Rivero A^{1,2}, Pascual M^{1,2}, Carreras C^{1,2}, Pegueroles C^{1,2,3}

POSTER SESSION 1 - P01.278, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Conservation genomic studies in non-model organisms often rely on reduced representation sequencing methods with restriction enzymes, such as Genotyping-by-Sequencing (GBS), which can be employed without reference genomes. Understanding the benefits and limitations of reference genomes in population genomic studies is essential to evaluate their importance. To test the impact of having or not a focal reference genome in conservation genomics, we analyzed GBS data from two ecosystem engineers, the sea urchins *Paracentrotus lividus* and *Arbacia lixula*. We analysed their population structure and identify candidate loci using two approaches: a) de novo analysis without reference genome to infer individual genotypes for population structure and candidate loci identification, followed by mapping to *Strongylocentrotus purpuratus* genome and functional assignment, and b) mapping, genotyping, population structure and candidate loci identification using the recently published focal reference genomes. For the two approaches functional

characterization was carried out using EggNogg mapper. Both approaches yielded the same overall population structure, but the use of reference genomes resulted in greater differentiation between populations and lower inbreeding coefficients. In the first approach, less than 10% of loci mapped to the closest reference genome initially available (*S. purpuratus*). In the second approach, using their respective genomes $\approx 95\%$ of loci mapped. Both methods revealed a higher frequency of loci in exonic regions, consistent with the GC content of the restriction enzyme's recognition site. However, the functional identification of candidate loci did not improve significantly due to the limited knowledge in gene functioning in Echinodermata. These findings emphasize the reliability of de novo population genomic studies using GBS and they highlight the substantial improvement in genomic characterization with a reference genome but not their annotation, showcasing the limitations of reference genomes of non-model organisms.

Tracing genomic consequences of historical sealing in South American fur seal populations

POSTER SESSION 1 - **P01.266**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Understanding the long-term genomic consequences of demographic history is central to evolutionary biology and conservation genomics. Demographic events such as population bottlenecks can leave lasting signatures in the genomic composition of populations - shaping genomic diversity, homozygosity, and accumulation of deleterious mutations. These signatures influence individuals' fitness and contribute to the adaptive potential of populations. Genomic data allow us to infer historical demographic events and evaluate how these past processes have shaped current patterns of genetic variation with implications for the future evolutionary trajectories of populations. Pinnipeds offer a 'natural experiment' for investigating how demographic histories leave lasting genomic signatures. Many pinniped species were heavily exploited by commercial sealers during the 18th and 19th centuries, resulting in bottlenecks of varying severity and duration. This variation makes them an ideal system to investigate these dynamics in a comparative framework.

Here, we focus on the South American fur seal (*Arctocephalus australis*), a species distributed across ~10,000 km of coastline along the Pacific and Atlantic coasts of South America. We compare Peruvian fur seals from the Punta San Juan marine protected area (Pacific coast) and Brazilian fur seals

from southern Brazil (Atlantic coast). While South American fur seals overall experienced moderate population declines due to sealing, historical records and genetic data suggest that the Peruvian population have undergone more severe and prolonged bottlenecks. In addition, the Peruvian fur seals is widely recognised as genetically distinct and has been suggested to be a separate evolutionary significant unit, likely shaped by both geographic barriers and historical demographic processes.

Using whole-genome resequencing data, we investigate how differences in demographic history affect genomic inbreeding, bottleneck strength, and genetic load. To do this, we estimate levels of inbreeding based on runs of homozygosity, reconstruct historical effective population sizes, and quantify putatively deleterious genetic variants. We expect to find evidence of a stronger bottleneck in the Peruvian population through demographic reconstruction. We hypothesise that the Peruvian population will show higher levels of genomic inbreeding and a higher burden of deleterious mutations compared to the Brazilian population. By quantifying and comparing these patterns, we aim to contribute to broaden our understanding of the long-term genomic consequences of historical demographic dynamics, and their potential impact on the fitness and resilience of wild populations.

Tracking Polygenic Adaptation: Phenotypic Stasis After Rapid Change in Large Populations of *Drosophila*

¹Institut Für Populationsgenetik, Vetmeduni, ²Vienna Graduate School of Population Genetics, Vetmeduni, ³Plattform Bioinformatik und Biostatistik, Vetmeduni, ⁴Max Planck Institute for Evolutionary Biology

POSTER SESSION 1 - P01.283, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Most quantitative traits are complex and their adaptation is driven by changes across many loci—polygenic adaptation. Most quantitative traits are under stabilizing selection which stabilizes the average trait mean on a specific value, i.e. trait optimum. Populations frequently experience environmental changes that shift the trait optimum, driving adaptation over short ecological timescales. Theory predicts that polygenic adaptation proceeds in two main phases: an initial directional phase characterized by shifts in the trait mean toward the new optimum, followed by a stabilizing phase in which the mean phenotype remains in equilibrium. However, the empirical data in support of the theoretical predictions is still lacking. We therefore aimed to empirically determine when adapting populations reached the new trait optimum after an environmental shift.

We quantified the phenotypic changes in replicate *Drosophila simulans* populations, each with 100,000 individuals, adapting to a new environment. An outbred founder population, created through round robin crosses of 93 inbred lines, was used to establish six large replicates that were exposed to a new high-protein diet for 31 generations in a laboratory environment. To track the evolutionary dynamics, we generated time-series high-order (fecundity, a fitness component) and molecular (gene expression) phenotypic data for the founder population (before the optimum shift) and the evolved replicates after 7 and 31 generations of maintenance on the high-protein diet. We characterized the trajectory of phenotypic adaptation and empirically inferred the transition between directional and stabilizing selection phases.

The fitness of evolving populations increased significantly at generation 7 (directional phase) then reached a plateau until generation 31. The directional phase was also characterized by a fast transcriptomic response at 7 generations involving more than 6000 differentially expressed genes (DEGs). After this rapid response, the expression of

a large proportion of the DEGs (64.73%, ‘plateau’ group) stabilized and reached a plateau until generation 31. The temporal patterns of gene expression are consistent with the patterns of fitness change suggesting the proximity of populations to the new trait optimum as early as generation 7. Patterns of parallel evolution indicated a high level of similarity among replicates where a high and consistent level of parallelism was observed in generations 7 and 31.

In addition to ‘plateau’ group other groups of DEGs with conserved patterns of co-expression were found. Two group of DEGs, ‘complete-reverse’ (11.17%) and ‘incomplete-reverse’ (5.30%) exhibited a reversal in the direction of expression change after generation 7 toward the ancestral population. Other group, ‘monotonic’ (7%) and ‘late-response’ (12.2%) showed a monotonous change in their expression until generation 31.

We computed the pleiotropic degrees of expressed genes using two independent measures: the tissue specificity and the level of connectivity in gene regulatory networks. Highly pleiotropic genes were less likely to be differentially expressed (i.e. constrained). However, groups of differentially expressed genes with transient responses (‘complete-reverse’ and ‘incomplete-reverse’ groups) exhibited the highest pleiotropy, suggesting the contribution of highly pleiotropic genes with large effect size in the initial phase of adaptation.

Here, we empirically inferred the transition between directional and stabilizing selection phases in populations adapting after an environmental shift confirming the predictions of theoretical studies. Our work helps bridge the gap between theoretical predictions and empirical evidence of polygenic adaptation over microevolutionary timescales. By combining experimental evolution with time-series phenotyping, we provide a framework to test and refine hypotheses about the mechanisms of adaptation.

Uncovering adaptive traits in legumes through novel genotyping approaches

POSTER SESSION 1 - P01.263, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The transition to plant-based diets is a crucial step toward ensuring sustainability of our agriculture and healthier dietary habits while contrasting and mitigating the impact of climate change. Legumes, due to their high protein content and ability to establish symbiotic nitrogen-fixing associations, represent a key resource for sustainable agriculture. Despite these advantages, genomic studies on food legumes are limited, which hinders breeding programs designed to promote their widespread use in agriculture. This is primarily due to the highly repetitive nature of plant species' genomes, which poses a major constraint on the large-scale sequencing of genotypes stored in germplasm banks, thereby limiting the comprehensive investigation of the biodiversity preserved across their numerous accessions. In this scenario, the GENUINE (Harnessing advanced Genomic mEthods to ideNtify fUture cllmate resilient geNotypes in lEgumes species with large and repetitive genomes) project aims to enhance the use of crop legumes as a natural resource for sustainable agriculture through the development of an innovative and cost-efficient genotyping platform.

Method: Specifically, the project focuses on: (i) Establish a sequencing pipeline based on Cas9 repeat-depletion system, designed to selectively remove highly repetitive, less informative genomic regions, (ii) applying this

approach to diverse genetic panels covering various agro-environmental regions, (iii) performing landscape genomics analyses to assess the impact of environmental and demographic factors on genetic variation, and (iv) integrating these findings with genome-wide association studies (GWAS) to identify genomic regions linked to both environmental adaptation and agronomic traits. The study will focus on lentil (*Lens culinaris*; ~3.69 Gb), pea (*Pisum sativum*; ~4.45 Gb), and faba bean (*Vicia faba*; ~13 Gb), three legumes of high nutritional and economic value that, given their prominent repetitive genomes (79% in faba bean, 84% in pea and lentil), will benefit from this technology. To this end, for each species a pool of accessions was selected to encompass their geographical diversity and, using passport data, we derived several environmental parameters which are crucial for landscape genomics experiments.

Results and Conclusions: Indeed, once the sequencing data were obtained, different statistical methods were implemented to correlate climate variables to genetic diversity identifying molecular traits linked with adaptation. Thanks to these results, it will be possible to guide breeding programs essential for improving legume cultivation, moving towards more sustainable agriculture and nutrition, and facilitating the adaptation of these species to future climate conditions driven by global warming.

Uncovering the genetic response of *Oikopleura dioica* against climate change-related biotoxins: insights into evolutionary enhance resilience

Torres Aguila N^{1,2}, Cassà-Garcia B¹, Ascione D³, Roncalli V³, Sánchez-Serna G⁴, Wibisana J⁴, Plessy C⁴, Luscombe N⁴, Cañestro C^{1,2}

POSTER SESSION 1 - P01.289, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Background: The impact of climate change on the evolution of genomes is not only important to understand how it affects biodiversity resilience from an evolutionary point of view, but also from an ecological perspective aiming to mitigate its impact. Particularly in marine environments, higher temperatures are causing the increase in harmful algae blooms, releasing natural toxins such as polyunsaturated aldehydes (PUAs) that impair animal fitness, fertilization and embryonic development. Nonetheless, we have shown that a cosmopolitan zooplanktonic tunicate, *Oikopleura dioica*, have evolved resilience to these toxins, being affected in a less severe manner. The unique characteristics of this fast-evolving chordate—such as genome plasticity and extensive gene losses—make it an attractive animal model to study, not only conserved compromised developmental pathways, but more importantly, potential evolutionary adaptations underlying its resilience.

Materials and methods: We performed RNA sequencing on control and PUA-treated embryos of *O. dioica* on different developmental stages, from pre-zygotic transcription activation (ZTA) stage to mid-embryonic developmental stage. The obtained data was used to perform differential expression analyses and Gene Ontology (GO) enrichment analyses to identify affected pathways. Finally, phylogenetic analyses were performed on candidate genes to explore their evolutionary conservation.

Results: We identified several differentially expressed genes (DEGs) on each one of the

embryonic stages studied, highlighting potential early PUA-response pathways. Surprisingly, a high proportion of DEGs (from 40% to 58%) lacked GO annotations, suggesting the involvement of apparent many lineage-specific genes. Nevertheless, GO enrichment analyses showed the glutamine-glutamate pathway together with the energy metabolism as the top enriched categories, both conserved pathways needed for essential physiological functions. Furthermore, *O. dioica* was found to have duplicated a central gene of the glutamine-glutamate pathway: *glutaminase (GLS)*, showing four gene copies, all of them up-regulated in response to PUAs. Phylogenetic analysis suggested these duplications are lineage-specific, potentially contributing to the species' enhanced resilience.

Conclusions: Our findings indicate that *O. dioica*'s genetic response to PUAs involves both conserved and potentially lineage-specific genes. The expansion and up-regulation of *GLS* genes point to an evolved molecular adaptation enhancing glutamine–glutamate pathway activity under biotoxin stress. Additionally, the high proportion of DEGs lacking functional annotation raises the possibility of a novel marine toxin-response network. Together, these findings provide a foundation for understanding the impact of climate change-related stressors on marine animals and offer insights into both conserved and lineage-specific evolutionary adaptations contributing to environmental resilience.

Using admixture to understand local adaptation in the common wood decay fungus *Trichaptum abietinum*

Lu D¹, Castellanos M¹, Andersen A¹, Helleland K¹, Solvik K¹, Methlie I¹, Kauserud H¹, Skrede I¹

¹University Of Oslo

POSTER SESSION 1 - **P01.297**, EXPO AREA, August 18, 2025, 5:00 PM - 7:00 PM

Trichaptum abietinum is a common wood decay fungus with a distribution that covers multiple climate zones. The widespread distribution of *T. abietinum* combined with its small genome size and ease of laboratory cultivation has sparked a growing number of population genomic and common garden studies. Previous studies have detected three genetic groups in Europe that likely originate from different glacial refugia. A Mediterranean group is found in Southern Europe whereas a Boreal group is distributed throughout Eastern Europe and most of Fennoscandia. These two groups form an admixture zone in central Europe where all the admixed individuals sampled to date have inherited the same large portion of a chromosome exclusively from the Boreal group. Wood decay rate experiments suggest heterosis in these admixed individuals in Central Europe as they have a faster decay rate than either parent population. A third Atlantic group has only been found in

Northwestern France and Western Norway. Fine scale sampling has revealed a narrow admixture zone between the Atlantic and Boreal groups in Norway. Interestingly, common garden experiments indicate that samples in Norway are better adapted to local conditions. The genetic regions involved these in adaptations are confounded with overall genetic structure since the distribution of the Atlantic group in Norway largely coincides with wet and mild climate, but the admixed individuals offer a way to control for this. Additional growth experiments with lab generated hybrids between the Atlantic and Boreal groups indicate that they are intermediates between the parent groups. We combine genetic, phenotypic, and bioclimatic data to identify genetic regions associated with local adaptation and try to understand these in light of the genomic landscape of introgression and recombination rate.

A locally adapted neotropical bromeliad shows loss of macrosynteny and expansion of stress related gene families among individuals along an elevational gradient

Aecyo P¹, Tavares M¹, Mattos J¹, Canal D¹, Canal D¹, Varani A², Pinheiro F¹, Chaves C¹, Bombarely A³, Riaño-Pachón D⁴, Palma-silva C¹

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

Local adaptation, a complex process driven by divergent natural selection, can involve both punctual mutations and extensive genomic rearrangements, affecting multiple metabolic pathways. Populations of the diploid bromeliad *Pitcairnia flammea* Lindl. display distinct phenotypic traits associated with ecological strategies along the elevation gradient of the Brazilian Atlantic Forest (from zero to ~2200 meters altitude). Our research aims to elucidate the genomic basis of local adaptation in *Pitcairnia flammea* Lindl. To achieve this, we assembled chromosome-level genomes of two individuals from contrasting altitudes (sea level vs. mountain) using PacBio HiFi and Omni-C sequences, and resequenced individuals with high-coverage Illumina short-reads from eight populations along an elevational gradient. The assembled genomes (1C = 500 Mbp) are highly contiguous, obtaining over 98% of Liliopsida BUSCO genes, but presenting large inversions in four chromosomes, encompassing ~170 genes in each genome. Both genomes are mainly composed of transposable elements (TEs), with five TE lineages particularly abundant in both genomes (i.e. Tekay, LARDs, SIRE, MITEs, TR_GAG), but showing variations between them. The PSMC analysis revealed that both individuals exhibited similar demographic histories, characterized by two population bottlenecks: one during the late Miocene (10 Mya) and the second during the Pliocene (1 Mya). The latter bottleneck coincides with an expansion of the LTR-TEs elements in both genomes. We detected an expansion of gene families in the mountain individual enriched

for GO terms related to water response, cold response, and lipid metabolism impacting several metabolic pathways, including the glycerophospholipid metabolism, which was previously reported to be involved in the adaptation to the temperature along the gradient in *P. flammea*. Moreover, the expanded gene families with these GO terms were duplicated and dispersed in the genome, with a higher density of the five previously identified TE lineages in their upstream and downstream regions compared to the rest of the genome. Thus, these results indicate that demography history or environmental pressure during the pliocene might have influenced the expansion of TE lineages. This expansion of TE might have played a role in expanding stress-related gene families, possibly mediating *P. flammea*'s adaptation to varying local environments along the elevational gradient. Notwithstanding, these results suggest that local adaptation in *P. flammea* populations might be driven by a complex interplay of multiple genes, diverse pathways, and changes in their genome architecture. The 81 individuals resequenced will be used to investigate the role of Single Nucleotide Polymorphisms (SNPs) and Structural Variations (SVs) in the adaptation process of *P. flammea*'s populations. Altogether, our study will contribute to a deeper understanding of the resilience of tropical mountain species to climate change, particularly in the world's most biodiverse region.

Adaptation to Multiple Environmental Stressors in *Tetrahymena thermophila*

Olazcuaga L¹, Philippe H¹, Legrand D¹

¹SETE, CNRS

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Understanding how natural populations adapt to simultaneous environmental stressors is essential in the context of global change, yet most evolutionary genomics studies focus on isolated stressors. This limits our ability to predict population responses to the complex, multifactorial pressures characteristic of anthropogenically altered ecosystems. To address this gap, we conducted a long-term experimental evolution study using the ciliate *Tetrahymena thermophila*, evolving six clonal lines for ~1200 asexual generations under elevated temperature, chemical pollution, or their combination—two common stressors intensified by climate change. We measured adaptation as fitness changes in the evolutionary environment and applied an evolve-and-resequence approach to identify and track de novo single

nucleotide polymorphisms (SNPs). Contrary to expectations, the number of de novo SNPs did not differ across treatments. However, fitness gains were marginally but positively associated with the mean frequency of these variants, regardless of stressor type or number. These results suggest that adaptation under complex environmental conditions can proceed without an increase in mutational input, potentially via subtle shifts in allele frequencies. Ongoing annotation of the *T. thermophila* genome will aid in linking these variants to functional pathways involved in stress response. Our findings underscore the importance of integrating experimental evolution with genomics to better understand polygenic adaptation and resilience in the face of climate-driven environmental change.

Adaptive introgression enhances heat tolerance despite barriers to gene flow: a case study in *Drosophila flavomontana* and *Drosophila montana*

Poikela N^{1,2}, Snook R³, Kulmuni J^{2,4}, Ritchie M¹

¹University of St Andrews, ²University of Helsinki, ³Stockholm University, ⁴University of Amsterdam

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

As global temperatures rise and heat waves become more frequent, populations must rapidly adapt to avoid local extinctions. Traditional adaptation through natural selection on new mutations or existing genetic variation has limitations. Hybridization and interspecific gene flow (introgression) offer an alternative route, allowing species to acquire pre-tested genetic material from close relatives. Few studies have experimentally tested the potential of adaptive introgression in response to warming temperatures, and investigated the interplay between adaptive introgression, barrier loci (regions of reduced gene flow), and recombination-suppressing chromosomal inversions.

Drosophila flavomontana's distribution is predicted to shrink due to increasing temperatures and the sterilizing effect of high temperatures on males. In contrast, *Drosophila montana* is more heat-tolerant, and therefore introgression from *D. montana* could aid *D. flavomontana* in adapting to heat. Despite diverging 2.5 million years ago, and possessing alternatively fixed inversions acting as potential drivers of speciation, the species can interbreed in the laboratory, making them ideal for studying gene flow and adaptation. We conducted a hybridize-evolve-and-re-sequence experiment to investigate whether heat exposure can facilitate the introgression of *D. montana* heat-tolerance alleles into *D. flavomontana* and improve heat tolerance. We also mapped long-term barriers between natural populations using a demographically explicit scan (gIMble) to explore whether

contemporary barriers observed in hybrids have also inhibited introgression throughout species divergence.

Heat-selected lines showed both improved male fertility under heat stress and greater introgression from *D. montana* compared to control lines. The X chromosome, with three overlapping inversions, showed no introgression in either heat-selected or control lines, indicating strong barriers to gene flow. In contrast, inversions on chromosomes 4 and 5 showed no introgression in control lines but some in heat-selected lines. The strongest correlation between male fertility and the amount of introgression was found in non-inverted regions of chromosome 4. Long-term barriers were also enriched within inversions and significantly overlapped with contemporary barriers.

Our results suggest that contemporary barriers observed in hybrids have acted as long-term barriers to introgression throughout species divergence, particularly within inversions. However, strong heat selection can overcome some of these barriers, especially in non-inverted regions and to some extent within autosomal inversions, facilitating the transfer of heat-adapted alleles between species and enhancing heat tolerance. While introgression has likely induced adaptation to warm temperatures, the levels of introgression were relatively low, and existing barriers appear to be strong enough to maintain species integrity.

Can Mediterranean Gorgonian Populations Cope with Extreme Climatic Events? Insights from Common Garden Experiments and Population Genomics in *Paramuricea clavata*.

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

Extreme climatic events (ECEs), such as marine heatwaves (MHWs), represent a significant and growing threat to marine biodiversity. Understanding the variability in ecological responses to recurrent ECEs within species, and the underlying drivers of this variability, is a key issue given its implications for conservation strategies and population recovery.

The red gorgonian, *Paramuricea clavata*, is a long-lived, habitat-forming octocoral dominating Mediterranean biogenic reefs. Shallow populations of this species have suffered mass mortality events due to recurrent MHWs over recent decades. Notably, field observations reveal variable mortality rates across populations, suggesting differing levels of thermal vulnerability and the potential for identifying both “resistant” and “sensitive” individuals—an insight that opens promising avenues for climate-resilient restoration efforts.

Here, we present the results of a collaborative effort that combines experiments in controlled conditions, genomics and population genetics, to characterize the drivers involved in the differential vulnerability to thermal stress.

In the first experiment, we exposed samples from 11 Mediterranean populations to thermal stress under common garden conditions to characterize response

variability across a broad spatial scale. From this, we re-sequenced the whole genome of 50 “resistant” and 50 “sensitive” individuals, and conducted a genome-wide association study (GWAS) to examine their genomic backgrounds. The results indicate no shared major-effect loci linked to thermal resistance, suggesting a complex or polygenic basis for this trait.

In a second experiment, we conducted repeated thermal stress tests over three consecutive years (2015–2017) using the same individual colonies. Statistical modeling highlighted the summer thermal regime prior to each experiment as the main factor influencing the response of *P. clavata* to thermal stress. Adaptive mechanisms—whether genetic or related to phenotypic plasticity—appeared to play only a limited role.

Overall, our results indicate that *P. clavata* has a constrained adaptive capacity to cope with the increasing frequency and intensity of marine heatwaves in the Mediterranean. We discuss the implications of these findings for the sourcing of individuals in climate-resilient restoration efforts. These findings raise important questions about the viability and effectiveness of current conservation and restoration strategies, emphasizing the need to reassess sourcing practices and long-term resilience goals for *P. clavata* in a warming Mediterranean.

Contrasting contemporary changes in large-effect life history loci in *Salmo salar* across Europe

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Understanding how wild populations evolve in changing environments is a central aim in evolutionary biology. In the last few decades, Atlantic salmon (*Salmo salar*) populations have been facing human-induced declines, as well as shifts in age at maturity and growth across their distribution. However, it is unclear whether these changes reflect evolutionary adaptation and how important large-effect loci are in this regard. Age at maturity, the number of years an individual spends feeding at sea before maturation, is an important fitness trait in Atlantic salmon. The genetic architecture of this trait includes two large-effect loci, *vgll3* and *six6*, which explain a substantial fraction of the phenotypic variation. The availability of long temporal data combined with this simple genetic architecture makes this trait a model for understanding contemporary evolution. In this study, by genotyping thousands of samples from long-term data collections across multiple wild Atlantic salmon

populations, we track the dynamics of change in the age at maturity trait and associated large-effect loci throughout the European range. Our results provide evidence for range-wide rapid adaptive evolution of some large-effect life history loci, but the direction and magnitude of change differs among populations. For example, somewhat surprisingly, opposing directions of allele frequency changes were observed in large effect loci in different populations. These findings illustrate heterogeneous adaptive responses in wild Atlantic salmon along a broad distribution spanning 42 to 65 years. Such responses are likely driven by different ecological and environmental pressures, such as riverine and marine fishing, water temperatures or the abundance of key prey species.

Keywords: Age at maturity, adaptive evolution, natural selection, life history, *Salmo salar*

Cryptic diversity and phylogeographic patterns in Mediterranean acrobat ants (*Crematogaster*) reveal complex evolutionary histories in response to climate change

Voges J^{1,2}, Blaimer B¹

¹Museum Für Naturkunde, Leibniz-Institut für Evolutions- und Biodiversitätsforschung, ²Humboldt University

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Understanding how insects have responded to past climate oscillations—through range shifts, migration, or adaptation—is crucial for refining future predictions and implementing effective conservation strategies. Yet, evolutionary histories of insects at the population level remain understudied. We address these critical questions by focusing on Mediterranean-wide distributed ants of the genus *Crematogaster*, one of the most species-rich and evolutionarily successful ant genera worldwide.

We investigated the *C. scutellaris* species complex, inhabiting ecologically dominant and behaviorally diverse members of Mediterranean ecosystems, playing key roles in shaping arthropod communities and influencing ecosystem dynamics. We generated low-coverage whole-genome sequencing (lcWGS) data for populations across their Mediterranean distribution. Genome-wide SNPs were analyzed to infer phylogenetic relationships, assess population structure, and detect cryptic diversity. BUSCO genes were used to evaluate genome completeness and support deeper phylogenetic signal. Genomic patterns were examined in regions of sympatry to explore introgression or hybridization events. In comparison, we analyzed populations of *C. sordidula*, another widespread Mediterranean ant species, using ultraconserved elements (UCEs) and SNPs to construct phylogenies, assess population structure, and estimate divergence times relative to historical habitat and climate changes.

Our analyses revealed deep genetic divergences within the *C. scutellaris*

complex, including a pronounced east–west split, a biogeographic pattern widely observed in Mediterranean taxa. Genome-wide data uncovered multiple genetically distinct clusters, suggesting extensive cryptic diversity undetectable through morphology alone. In zones of sympatry, particularly on the Balkan Peninsula, our data indicates historical and possibly ongoing hybridization. These findings point to dynamic population interactions in areas shaped by fluctuating environmental conditions. For *C. sordidula*, genomic data revealed comparable east–west differentiation, with divergence times corresponding to major climatic and geological events during the Pleistocene. The Aegean region and the Balkan Peninsula exhibited especially complex population dynamics, reflecting habitat complexity shaped by intense climatic oscillations. Southern Mediterranean refugia, which remained relatively stable during these climate shifts, emerged as critical centers for lineage persistence across species.

Our study reveals a complex evolutionary history in *Crematogaster* ants shaped by repeated climate and habitat changes. Genome-wide molecular data provide strong support for the molecular delineation of cryptic lineages and uncover a more intricate evolutionary history and complex population structures than previously inferred from morphology alone. These insights contribute to a deeper understanding of insect response to past habitat changes and inform predictions about their adaptability in the face of future climatic challenges.

Deep-time genomes reveal the evolution of distinct genetic variants in the woolly mammoth

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

The unique characteristics of a species' genome result from evolutionary changes accumulated across considerable timescales, often exceeding several hundreds of thousands of years. While comparative genomics allows for the identification of genome architecture changes across species, pinpointing the exact timing and rate of these evolutionary changes remains challenging when relying on modern snapshot data alone. The Pleistocene evolution of mammoths in Eurasia represents a framework for studying the evolutionary processes of environmental adaptation and speciation in changing climates. Here we sequenced 29 late-Pleistocene woolly mammoth genomes as well as two mid-Pleistocene mammoths, dated to 1.1 and 0.7 million years old. Combining this with 64 additional woolly

mammoth, African elephant, and Asian elephant genomes, we identified the protein-coding and regulatory region changes that underlie the formation and speciation of the woolly mammoth across a million-year time transect. We find that most functional changes for cold climates and high latitudes in woolly mammoths evolved in the time before the first woolly mammoths appear in the fossil record around 0.7 million years ago. Genes involved in fat metabolism, thermoregulation, and immune system functioning have been under continuous selection in woolly mammoths up to their extinction, whereas genes involved in fur and hair development, circadian rhythm, and taste and smell perception had already highly evolved in the mid-Pleistocene mammoths and remained stable since.

Effect of temperature on viability selection of developing hybrids revealed by whole genome pool-seq

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Hybridization is now known to be pervasive across the tree of life and to have deleterious consequences, e.g. selection against hybrid incompatibilities. However, it can also allow for fast adaptation to changing environments via adaptive introgression or by increased genetic diversity that allows for faster adaptation. With higher temperatures and frequency of extreme events due to climate change, species ranges are predicted to shift and bring previously geographically isolated species or populations into contact, increasing hybridization rates. Further, recent research has proposed that hybrid plants and animals might have increased fitness under climate change. Thus, it is necessary to understand if hybridization in the context of climate change will be adaptive (i.e., allow admixed populations to better adapt to their fast changing environments) or deleterious (e.g., due to selection against hybrid incompatibilities). An outstanding system to study these questions can be found in Southern Finland, where the mound-building wood ants *Formica aquilonia* and *F. polyctena* have hybridized and produced several hybrid populations. Thermal stress experiments have shown that the parental species are divergently adapted to temperature (*F. polyctena* is warm-adapted, while *F. aquilonia* is cold-adapted) and that hybrids are as tolerant to heat as their warm-adapted parental species. In haploid

hybrid males, the frequency of cold-adapted alleles rises in colder years and that of warm-adapted alleles rises in warmer years. Hence, temperature is likely a key selective pressure to which hybrids can respond quickly. However, this increased thermal resistance was observed in adult workers; how are hybrid queens and their offspring affected by temperature? To address this, we exposed hybrid and cold-adapted parental queens to different temperatures and compared their egg-laying and hatching rates. We show that the higher thermal tolerances to different temperatures found in adult hybrid and parental workers are absent during early development. We found that low temperature is a severe selective pressure for both hybrids and parentals. The hatching rate of hybrid eggs was reduced compared to parental eggs at high temperature, which could be explained by environment-dependent hybrid incompatibilities. Ongoing analysis of pooled whole genome sequencing data obtained from eggs and larvae collected from this experiment will unravel signatures of intrinsic and environment-dependent incompatibilities, allowing us to quantify the strength of selection against incompatibilities across the genome. Overall, we show that developing individuals need to overcome the deleterious effects of hybridization during development to reap its benefits in adulthood.

Environmental effects on the origin and establishment of *Arabidopsis arenosa*

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

The effect of the environment on the establishment of polyploidy has been a long-term mystery, and it has been hypothesized that polyploids are better adapted to temperature extremes than their diploid progenitors. Given the increasing challenges that plants and animals face due to global warming, this study explores polyploids' molecular basis of their adaptation to thermal and precipitation fluctuations, using *Arabidopsis arenosa* from the family Brassicaceae as the model system. This species crosses multiple climatic zones along its distribution, and its various intraspecific lineages adapted to diverse environmental conditions, including northern latitudes. In this study, I utilized the first pan-genome of *A. arenosa* and genotype-environment association analysis with 254 genome-sequenced diploid and 510 tetraploid populations (total 764 individuals) to investigate the impact of harsh environments on the adaptation of *A.*

arenosa, namely selected genes. Also, the genetic offset was used to predict the maladaptation comparing diploids with tetraploids. Based on the initial findings from this analysis, significant differences in single nucleotide polymorphisms strongly associated with the coldest temperature in the coldest month and precipitation of the driest month were observed between diploids and tetraploids. Our preliminary findings indicate that genes strongly associated with cold temperatures in tetraploid *A. arenosa* encompass both stress response and DNA regulation, while for precipitation genes involved in signaling receptor response to stress were found specifically in tetraploids. This may explain why tetraploids exhibit a robust adaptation to wider environmental regimes, although it is not significantly stronger compared to their diploid progenitors.

Evolutionary genomic predicts Adaptation, Maladaptation, and Plastic Expression Responses to Climate Change in Two Closely Related Species with Contrasting Distribution Ranges and Population Sizes

Dan X¹, Wang Z¹, Gong Y¹, Sang Y¹, Wang J¹

¹Sichuan University

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Background: Climate change is transforming ecosystems globally, exerting selective pressures that threaten the survival of many species, including forest tree species that play crucial ecological roles in maintaining the structure and function of terrestrial ecosystems. The ability to adapt, avoid maladaptation, or exhibit plasticity in response to environmental changes is essential for species' persistence under such conditions. Evolutionary genomics provides a powerful framework to investigate these dynamics by identifying genetic variants associated with climate adaptation, quantifying genomic vulnerability and genetic load under future climate scenarios, and analyzing gene expression plasticity as an immediate response to stress.

Materials and methods: In this study, we focused on two closely related species with contrasting ecological and demographic characteristics: *Populus adenopoda*, a widespread subtropical mainland species inhabiting diverse environments across East Asia, and its sister species, *Populus qiongdaoensis*, a tropical island species restricted to Hainan Island with small population sizes. We generated high-depth whole-genome resequencing datasets for 228 individuals sampled from 32 populations of *P. adenopoda* and 5 populations of *P. qiongdaoensis*.

Using this dataset, we first reconstructed the phylogenetic relationships between the two species, inferred their divergence history, and analyzed the population structure of their current populations. Next, we applied various approaches to assess and compare future habitat suitability, the accumulation of deleterious mutation loads, and genomic offsets to future climate change across all populations within the distribution ranges of both species. This allowed us to evaluate the adaptive capacity and the ecological and genomic vulnerabilities of these populations and species. Finally, we assessed the extent of gene expression plasticity in response to immediate environmental stresses by performing greenhouse experiments. These experiments involved collecting gene expression profiles from both leaf

and root tissues of seedlings from both species under control and environmental stress conditions, including heat and waterlogging.

Results: First, our results revealed that *P. adenopoda* and *P. qiongdaoensis* diverged approximately 2.51 million years ago during the Quaternary glacial period. Following their divergence, *P. qiongdaoensis* experienced a continuous population decline, whereas *P. adenopoda* likely contracted into three major refugia and underwent substantial population expansion, eventually spreading across the subtropical mainland of East Asia after the Last Glacial Maximum, around 20,000 years ago.

Second, compared to the widespread species *P. adenopoda*, the island species *P. qiongdaoensis* exhibited significantly lower genetic diversity, a higher genetic load, and greater genomic vulnerability to future climate change. As the island species cannot migrate to more suitable habitats, assisted gene flow appears to be a promising strategy for mitigating maladaptation. Through an integrative approach, we identified optimal locations and adaptive genes within the range of *P. adenopoda* that could effectively transfer adaptive variants via assisted gene flow to support the survival and adaptation of *P. qiongdaoensis*.

Lastly, we examined and compared the expression plasticity induced by instant environmental stresses in seedlings of both species under greenhouse conditions. This analysis provided insights into the relative contributions of adaptive and non-adaptive plastic expression responses in facilitating adaptation to novel environments.

Conclusions: By integrating ecological, genomic, and transcriptomic data, our study explores how demographic history, genetic diversity, and environmental exposure shape adaptation and maladaptation in two sister *Populus* species with contrasting characteristics. These findings provide valuable insights for conservation strategies, including assisted gene flow and genetic rescue, to mitigate climate-driven risks for the island species.

Evolutionary trajectories of plasticity when encountering novel thermal conditions during range expansion in the wild

¹KU Leuven, ²Royal Belgian Institute of Natural Sciences, ³University of Seville, ⁴Instituto de Ecología

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Despite the theoretical importance of plasticity for the speed of adaptation to novel environments, empirical data on the evolutionary trajectory of plasticity in new selective regimes are very limited in the wild. We harnessed range expansions of a damselfly from France into warmer regions in Spain as a natural experiment to test how transcriptional thermal plasticity evolves, and compared the outcomes with a native, locally thermally adapted sister species. A common-garden experiment of 11 populations revealed that plasticity evolution depended on the magnitude and duration of the warming treatment, with

stressful high temperatures causing maintenance of plasticity. The frequency of plastic genes that becomes assimilated is higher with increasing duration of historical exposure to the thermal regime and when the warming treatment is more often encountered. Overall transcriptomic plasticity first increased and subsequently decreased during range expansion, indicating evolved plastic responses precede evolutionary adaptations when coping with new thermal environments. These findings are crucial to predict the role of plasticity in driving evolution in a warming world.

Genes that underlie photoreception and seasonal reproduction are crucial for local adaptation in the Northern krill, a keystone zooplankton for the North Atlantic Ocean

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Krill are superabundant pelagic crustaceans that play crucial roles in ocean food webs and influence global climate by acting as ocean carbon sinks (Trinh et al, 2023). Climate change is strongly impacting the distribution and well-being of krill populations (Veytia et al, 2020), but little is known about the adaptive potential of krill species to a changing environment. To date, genetic studies of krill have been hampered by their large genome sizes. In contrast to polar species like the Antarctic krill, the boreal Northern krill, *Meganyctiphanes norvegica*, is adapted to both warm and cold water, and therefore serves as a good model system for adaptation. To better understand processes of genetic adaptation in Northern krill, we performed de novo genome assembly and population genomics on 74 individuals from 8 populations distributed over the North Atlantic Ocean and the Mediterranean Sea (Unneberg et al., 2024).

We used multiple DNA sequencing technologies to generate a 19 Gbp reference genome assembly of a female specimen in the Gullmarsfjord, Sweden. The genome is highly repetitive and has evolved through wide-spread proliferation of retrotransposons, now targeted for inactivation by an active DNA methylation system. In addition, gene families for photoreception and molting are greatly expanded through gene duplication, which suggests adaptation to temperature and light.

We resequenced 74 individuals from 8 populations and compiled a dataset consisting of ~760 million SNPs. Genetic variation analyses revealed moderate levels of genetic diversity (~1.4% overall) and identified extensive homogenizing gene flow. Nevertheless, hundreds of genomic loci did show highly divergent allele frequencies between populations, likely due to selection for local adaptation. Candidate genes showing signs of adaptation were predominantly

involved in photoreception, circadian rhythm, reproduction and thermal tolerance. The top candidate gene was *nrf-6*, a gene that codes for a protein involved in ovary maturation and oogenesis. One haplotype is fixed in the Mediterranean population and could be a locally adapted reproductive behavior to early spring phytoplankton blooms.

With our work, we have established the Northern krill as a model for ecological, evolutionary, and population genomics in zooplankton. Our variation data and candidate gene list is a valuable resource for researchers who study the link between genetic variation and adaptation. A better understanding of genetic adaptations of krill will contribute to improved predictions of their long-term responses to environmental changes and provide guidance for stock management and conservation efforts.

Genetic variation in the response to multiple stresses: the case of *Lymnaea stagnalis* exposed to metals and global warming

Aimon C¹, McCairns S¹, Marie-Agnès C¹

¹DECOD - Dynamique et durabilité des écosystèmes : de la source à l'océan, Ifremer, INRAE, L'Institut Agro

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Background: Climate change and pollution are among the five most important threats posed to biodiversity (Parmesan et al. 2022). Besides, it is now admitted that the unprecedented levels of environmental stress undergone by biodiversity lead to time scale overlaps between ecological and evolutionary responses (Carroll et al. 2007). As chemical pollutants constitute potent sources of environmental stress, their ability to trigger micro-evolutionary processes in exposed populations is increasingly studied. Understanding the evolutionary impact of these pollutants is also a new challenge for ecological risk assessment, especially in the context of global change where populations are often exposed to complex cocktails of contaminants along with other anthropogenic and natural stressors, which may interact in various ways. Therefore, it has become critical to assess chemicals' long-term ecological risk under various climatic scenarios.

A first step towards this end is to evaluate the genetic variability in stress responses, upon which selection might operate. In the present study, we addressed this issue by assessing the between-population variability in transcriptomic responses of a model invertebrate to trace metallic elements (as widespread persistent contaminants) and warming. We chose copper, as an essential element that becomes toxic at high doses, which is widespread and used as pesticide even in organic agriculture, and lithium, as an emergent contaminant associated with the development of digital technologies).

Materials and methods: To this end, seven day-old F1s obtained in the laboratory from adults collected in five populations or strains of the great pondsnail *Lymnaea stagnalis*, were exposed for three weeks (juvenile period) to a sublethal concentration of lithium (100 µg/L) and copper (20 µg/L), separately or as a mixture, under two temperature regimes (20°C, considered as optimal under local conditions,

and 24°C, following a +4° warming scenario). The effects of metals and temperature were estimated on transcriptomic expression (differential expression relative to controls, RNAseq), together with snail growth and cardiac frequency, and compared across populations.

Results: Growth was faster at 24°C than at 20°C, reduced under copper exposure, and not affected by lithium. The two factors interacted significantly with the factor population, indicating genotype x environment interactions at the level of populations.

Cardiac activity was negatively related to age and size, and this relation was steeper at 24°C, especially under lithium and control conditions (Temperature by Metal interaction). Population had no effect alone nor interacted with other factors on this trait.

Transcriptomic analysis (Deseq2) showed a main effect of temperature, with 711 differentially expressed genes (DEGs). Among these, only 68 DEGs were shared by the five population. Lithium had almost no detectable effect on the transcriptome, whereas copper exposure induced substantial differential expression (538 DEGs), with no gene found in common among the five populations. While these results reflect a strong influence of the genetic background on the response of *L. stagnalis* to the tested factors, the functional significance of this between-population component of transcriptomic expression is currently explored through annotation (with a particular attention to regulatory factors) and enrichment analyses, which will be presented at the conference.

Conclusions: The present results suggest that a species ability to cope with thermal and metal stress, as well as their combination, depends strongly on the population genetic background. Such interactions indicate that current ecological risk assessment of chemicals, which ignore warming and genetic influences, may be underprotective.

Genomic bases of short term evolution in the wild revealed by long term monitoring and population-scale sequencing.

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

Understanding how populations rapidly adapt to changing environments requires uncovering the genomic basis of heritable traits and examining how these traits evolve over short timescales. This challenge is particularly acute in wild, non-model species, where disentangling genetic and environmental contributions to phenotypic variation demands extensive phenotypic and genomic resources. The long-term study of the Swiss barn owl (*Tyto alba*) population provides a rare and powerful framework for addressing this challenge. Over the past 30 years, we have observed a striking evolutionary trend: individuals are becoming darker and more spotted—two melanin-related traits that were previously linked to fitness. Leveraging whole-genome

sequencing of over 3,000 individuals, we show that these two traits are controlled by a few loci with substantial effect sizes and exhibit a partially overlapping genomic architecture. Temporal allele frequency tracking at these loci shows subtle yet consistent changes. Using simulations, we show that these changes align with patterns expected under selection. By illuminating the genomic mechanisms underlying rapid phenotypic evolution in a wild population, this study provides critical insights into how fitness-related traits evolve in response to environmental pressures. In the context of accelerating climate change, our findings underscore the potential for adaptive responses in natural populations.

Genomic signals of adaptation during replicate range shifts of the blue-tailed damselfly, *Ischnura elegans*, in Scotland and Fennoscandia

Lustenhouwer N¹, Layton K², Dudaniec R³, Fitt R⁴, Hansson B⁵, Penny L^{1,6}, Svensson E⁵, Wellenreuther M^{7,8}, Williamson M¹, Lancaster L¹

¹University Of Aberdeen, ²University of Toronto, ³Macquarie University, ⁴University of Liverpool, ⁵Lund University, ⁶University of Exeter, ⁷University of Auckland, ⁸Plant and Food Research

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

With climate change, range shifts to higher latitudes are now widely observed across plants and animals. Recent work has shown that range-expanding populations can rapidly adapt to new environments, fundamentally changing the expansion velocity and final range limit. However, the genomic changes underlying range shifts in wild populations are still poorly understood. How variable and predictable are genomic changes during climate-mediated range shifts, and how do environmental gradients affect gene flow, drift, and adaptation?

We explored these questions along four replicate range-shifting transects of the blue-tailed damselfly, *Ischnura elegans*, in Scotland, Norway, Sweden, and Finland. This species is rapidly expanding its native range northward, consistent with insects showing especially rapid poleward movement in response to climate change. We conducted low-coverage whole genome sequencing of 957 individuals from 81 sites spanning 1700km. To study neutral and adaptive genomic changes along the transects, we analyzed the sequencing data using a genotype likelihood framework in ANGSD. We conducted a Genome-Environment

Association analysis across the genome for each transect separately, and then compared putatively adaptive SNPs across the transects in windows of 10 kbp using PicMin, a statistical tool designed to detect repeated adaptation in genome scans.

Population structure strongly differed between the transects, consistent with regional differences in dispersal barriers in the landscape. We found 61 genomic windows that showed significant association with the environment across all 4 transects, with temperature being more important than precipitation. Outlier windows revealed candidate loci with annotations relevant for poleward movement including the circadian clock, development and immune function. Using local PCA, we identified a putative structural variant that was more common in cold environments and associated with neuropeptide receptors involved in insect feeding, locomotor activity and circadian rhythms. By comparing parallel outlier loci with idiosyncratic outliers unique to individual transects, we aim to better understand the genomic drivers of adaptation during range shifts.

Local adaptation and forecasting response in the endangered Scottish freshwater pearl mussel

Gillman V¹, Pritchard V², Lancaster L¹, Piertney S¹, Layton K^{1,3}

¹University of Aberdeen, ²University of the Highlands and Islands, ³University of Toronto

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

Given the rapid pace of climate change, there is an urgent need to understand how endangered species will respond to changes in their environment. Species distribution modelling is a popular tool used to forecast a species range based on the relationship between surveyed occurrence data and explanatory (habitat) factors. However, it does not account for local adaptation and intraspecific response to change. Genomic offset offers an evolutionary dimension for forecasting species response to change and is defined as the mismatch between current adaptive composition and future optimal composition under a changed environment. The freshwater pearl mussel, *Margaritifera margaritifera*, has a widespread Holarctic distribution but many constituent populations are endangered or threatened. Scottish populations have a complex pattern of genomic population structure, partially explained by local climate. Here, we compare predictions from an ensemble species distribution model (SDM) of 462 presence points of *M. margaritifera* with

genomic offset estimates derived from 417 putatively adaptive SNPs from 18 populations in Scotland. Both the SDM and genomic offset forecast a loss of *M. margaritifera* from the eastern Scottish Highlands, with loss of suitable habitat and maladaptation of local populations. However, while the SDM indicates a future loss of suitable habitat on the Ardnamurchan Peninsula, these populations have a lower value of genomic offset suggesting these populations are more resilient to climate change through existing adaptation. As such, these findings indicate that although general trends are congruent among methods, there are fine scale differences that may go undetected without considering genomic composition. This study examines the use of both species distribution models and genomic offset and demonstrates the utility of an evolutionary perspective alongside species distribution models for forecasting species response to a changing climate.

Local Adaptation to Climate in Wild and Feral Brassica rapa: Genetic Architecture and Genetic Offset

¹UMR AGAP Institut, Univ Montpellier, CIRAD, INRAE, Institut Agro, F-34398 Montpellier, France, ²UMR CBGP (INRAE – IRD – Cirad – Montpellier SupAgro), Campus International de Baillarguet, CS 30016, F-34988 Montpellier-sur-Lez Cedex, France, ³IGEPP, INRAE, Institut Agro, Université de Rennes, 35650 Le Rheu, France

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

As climate change drives rapid environmental shifts, crops face significant challenges due to their limited genetic diversity, which constrains their adaptive potential. Crop wild relatives—and potentially feral populations, which are wild populations derived from domesticated ones—are likely to be locally adapted to diverse environments and could serve as valuable reservoirs of genetic diversity for breeding and crop improvement. Exploring and conserving this genetic diversity is essential, as it preserves a broad spectrum of adaptations to varied environmental conditions.

In this study, we investigate the genetic basis of local adaptation to climate and potential mismatches under future conditions in *Brassica rapa* (field mustard), a wild relative of turnip, Chinese cabbage, and pak choi, and a genome donor for *Brassica napus* (rapeseed). Seeds were collected through the BrasExplor project—a consortium coordinated by IGEPP (INRAE) with 11 partners from seven countries. A total of 62 spontaneous populations were sampled in Algeria, France, Italy, and Slovenia, revealing strong genetic structure between feral populations (from continental Europe) and wild populations (from Algeria and Sicily).

We conducted genome–environment association analyses and applied the local score approach to identify highly significant genomic regions associated with climatic variables, including promising variants and candidate genes. However, broader genomic patterns suggest that adaptation to climate is not limited to a few loci but likely reflects a

polygenic architecture involving multiple regions across the genome. While the inclusion of feral populations allows exploration of a broader climatic envelope and identifies variants potentially easier to introgress into crops, their reduced genetic diversity—likely due to domestication and rewilding bottlenecks—may limit our ability to capture the full spectrum of adaptive variation present in truly wild populations. This hypothesis was confirmed by repeating the analysis on a subset of wild populations, revealing a large number of additional candidate regions.

We also conducted genomic offset (GO) analyses to estimate the potential mismatch between current allele frequencies and those expected under future climates. Several populations showed high GO values, suggesting nonoptimal allele frequencies in their future climate. Phenotypic data obtained in a common garden experiment indicated that GO may partially predict variation in fitness, but this relationship should be interpreted with caution. More specifically, fitness proxies (seed number and weight) may be biased in feral populations, and much of the adaptive signal specific to wild populations is not captured, limiting predictive power for those populations.

These findings highlight the complex genetic architecture of climate adaptation in *B. rapa* and underscore both the potential and the limitations of genomic tools for guiding conservation and crop improvement strategies in a changing climate.

Plasticity, local adaptation and maladaptation to climate in a wild relative of the cultivated apples

Dadole R¹, Chen X², Sandoval J¹, Venon A², Criado M¹, Delprouve N¹, Kirisits T³, Ursu T⁴, Roman A⁴, Volk G⁸, Alins G⁵, Remoue C¹, Avia K⁷, Marchadier E¹, Bazot S⁶, Conde e Silva N¹, Cornille A²

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

Understanding how perennial species respond and adapt to climatic variation is essential to predicting plant resilience in changing environments. While plastic responses allow individuals to cope with environmental heterogeneity, they may also mask or facilitate local adaptation, especially in long-lived species with broad distributions.

In this study, we combined field experiments, transcriptomics, and population genomics to assess the relative roles of phenotypic plasticity, gene expression divergence, and adaptive potential in the domesticated apple (*Malus domestica*) and its wild relatives *M. sylvestris* and *M. orientalis*. We grew 894 seedlings from 46 populations in four common gardens simulating distinct climates and measured 12 functional traits related to growth, resource allocation, and stress. Gene expression was quantified in 96 seedlings under contrasting conditions, and population-level variation in gene expression plasticity was linked to SNP-based genome–environment associations and estimates of mutational load.

Climate strongly shaped seedling growth and physiology, explaining most of the phenotypic variance across species. All species displayed high plasticity, but *M. orientalis* showed greater phenotypic stability across environments than *M.*

sylvestris, while domesticated apple was highly plastic but suffered reduced performance in stressful environments. Genes differentially expressed between climates (climate-DEGs) were highly modular, enriched in nutrient and defense functions, and partially overlapped with loci showing signatures of climatic adaptation from GEA analyses, suggesting a genomic basis for adaptive plasticity. Finally, analysis of putatively deleterious mutations revealed a lower mutational burden in *M. domestica* compared to wild relatives across all gene categories. Notably, climate-DEGs carried fewer deleterious variants than non-DEGs, implying stronger purifying selection on environmentally responsive genes. The Romanian *M. sylvestris* population consistently harbored the highest genetic load, possibly reflecting demographic bottlenecks and reduced efficacy of selection.

Together, our findings show that climate-driven plasticity in apples is widespread but structured, involving genes under stronger selection and contributing to differential resilience across populations. This integrative framework combining ecology, expression, and genomics helps clarify the complex interplay between plasticity, adaptation, and genetic load in perennial fruit trees.

Spatial scales of genomic adaptation to climate and phenology in the winter moth

Estandia A¹, Learmonth R¹, Beaupère L¹, Merino Recalde N¹, Phillimore A², Sheldon B¹

¹University of Oxford, ²University of Edinburgh

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

Climate change is altering global ecological conditions, and a key challenge is understanding how quickly populations can adapt to rising temperatures. Seasonal timing traits provide some of the best evidence of phenotypic responses to climate change, including rare but compelling examples of genetic adaptation. When trophic interactions impose strong selection on phenological traits—as in the case of winter moth larvae needing to hatch in synchrony with deciduous tree leaf-out—they offer powerful models for studying evolutionary responses. However, we still lack a clear understanding of the spatial scale, genomic architecture, and environmental drivers of such adaptation. Here, we investigate the genomics of adaptation to climate and host phenology in

the winter moth (*Operophtera brumata*), an important prey species for insectivorous birds like the great tit. We sequenced 151 whole genomes from 16 sites across the UK, encompassing a wide range of spatial scales (pairwise distances from 1 to 1100 km), altitudes (from sea level to 200 m), and climatic conditions (mean spring temperature range: ~7–17°C). We first assess population structure and model dispersal to determine the scale at which local adaptation might occur. We then combine gene–environment associations, selection scans, and structural variant discovery to uncover the genomic basis of adaptation. Our results provide new insights into the evolutionary potential of seasonal timing traits and the capacity of species to respond to rapid environmental change.

Speciation under stress: Genomic and ecological divergence in Eastern Baltic Cod

Han K¹, Barth J², Breuninger N¹, Hoff S³, Helmerson C³, Jacobsen K³, Jentoft S³, Reusch T¹

¹Geomar Helmholtz Centre For Ocean Research Kiel, ²University of Basel, ³University of Oslo

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

Marginal populations at the distribution edge of a species are often more vulnerable to environmental stressors than core populations. When such marginal populations are exposed to additional human-induced impacts—such as overfishing, habitat degradation, and climate change—they may suffer disproportionate declines, particularly if they are already ecologically and genetically distinct from neighboring groups. The Eastern Baltic Cod (EBC) exemplifies above scenario and has experienced a severe and ongoing collapse marked by the loss of spawning grounds, sharp declines in population size, body condition, and body size, likely driven by intense fishing pressure and challenging environmental conditions such as increasing hypoxia. Having diverged from the Western Baltic cod approximately 7,000 years ago, EBC has since rapidly adapted to the unique environmental conditions of the Baltic Sea such as low salinity and oxygen level. Evidence suggests strong reproductive

barriers between the two populations, including mismatches in spawning time and location, and the notable absence of adult hybrids in the wild—hallmarks of ongoing speciation. In this study, we synthesize existing knowledge on reproductive isolation and apply genomic tools to identify and quantify hybridization across life stages. Leveraging a new reference genome for EBC, we also investigate genome-wide divergence and infer the population's demographic history. Recognizing EBC as a genetically distinct species has critical implications for management and conservation. If reproductive isolation is strong, this population cannot be replenished from the west upon collapse. Thus, reframing EBC as a separate evolutionary unit calls for urgent reassessment of current stock management practices and the development of conservation strategies that reflect true population boundaries.

Strong Selection, but low repeatability: Temperature-specific effects on genomic predictions of adaptation

Berger D¹, Rego A^{1,2}, Baur J¹, Girard-Tercieux C³, Celorio-Mancera M², Stelkens R²

¹Uppsala University, ²Stockholm University, ³University of Toulouse

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

Background: Climate change is causing major shifts in species' distributions, interactions, and growth rates across the globe. Predicting these shifts is thus of fundamental ecological and economical importance but remains a major challenge. One particularly promising avenue for making forecasts is to use genomic methods, such as "genomic offsets", to predict the level of (mal)adaptation and evolutionary potential of wild populations which' demography and life-history is hard to monitor, but for which whole-genome DNA sequences can be attained. However, the accuracy of such methods is currently debated and seldom validated.

Rationale: Climate warming is currently increasing temperatures beyond the optima of many ectotherms, placing many natural populations under risk and emphasising the need to evaluate our predictive power to forecast species responses to future warming climates. However, the strong selection on basal physiological and metabolic processes imposed by hot temperature also suggests that, when it happens, adaptation to warming should be relatively fast and predictable. Here, we evaluated the potential to predict adaptation

to hot and cold temperature, from the level of single nucleotide polymorphisms to life-history traits, by conducting an evolve-and-resequence experiment using replicate strains of three geographically separated populations of the cosmopolitan insect pest, *Callosobruchus maculatus*.

Findings: Indeed, adaptive evolution of life-history traits was faster and more repeatable at hot temperature. However, while genomic adaptation to heat was repeatable and showed signs of gene re-use across replicate lines of the same genetic background, it was much less repeatable than cold adaptation when compared across genetic backgrounds. As a result, genomic predictions of phenotypic (mal)adaptation to hot temperature were accurate when applied to populations of the same geographic origin but were highly inaccurate when applied to populations of different geographic origin. These results seem best explained by an increased importance of genetic redundancy and epistasis during adaptation to heat and imply that genomic predictions of adaptation in key life-history traits, which mediate the agricultural impact of insect pests, may become increasingly difficult as climate warms.

The genetics of thermal adaption in tropical butterflies

Nadeau N¹, Nguyen T¹, Salazar P^{1,2}, Smith S^{1,3}, Gavilanes K⁴, Guachamín M⁴, Bacquet C⁴

¹University Of Sheffield, ²Tree of Life Programme, Wellcome Sanger Institute, ³Centre for Molecular Biodiversity Research, Leibniz Institute for the Analysis of Biodiversity Change, ⁴Universidad Regional Amazónica IKIAM

MEETING ROOM 114, August 18, 2025, 10:30 AM - 12:30 PM

Background: Climatic stratifications, in particular differences in temperature, along altitudinal clines, can lead to local adaptation and genetic divergence between populations at different altitudes. Year-round stable temperatures in the tropics make altitudinal temperature variation more pronounced and increase the likelihood of local adaptation across relatively narrow gradients. This, combined with tropical species often living close to their thermal maximum, has been used to argue that tropical species may be particularly threatened by increasing temperatures. However, genetic variation present within species across altitudinal clines may also provide the necessary raw material for natural selection to act on in response to changing climates.

Methods: Here we focus on two butterfly species, *Heliconius erato* and *Heliconius melpomene* which co-occur from sea-level up to just over 1000 meters above sea level on the slope of the Andes. We used controlled rearing identify and tease apart

phenotypic variation due to genetic differences between populations and due to the plastic effects of rearing temperature as well as traits that show genotype-by-environment interactions. We then conducted transcriptomics to understand the genes underlying these differences.

Results: We found evidence of developmental, morphological, and thermal tolerance variation associated with location of origin, rearing temperature, or an interaction between these. In particular, *H. erato* showed strong evidence of adaptive plasticity in response to heat, with increased heat knockout times at higher rearing temperatures, but only in the populations from low altitude. Our transcriptomic results have identified heat shock proteins that may be responsible for this variation.

Conclusion: These results provide new insights into thermal adaptation in tropical insects and the genetic basis of plasticity, which may prove adaptive as species respond to changing climates.

Unveiling future maladaptation and preadaptation in locally adapted Mediterranean beech populations under climate change

¹Universitat De Barcelona (UB), ²Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAe URFM), ³Alt Pirineu Natural Park, ⁴Centre de Recerca Ecològica i Aplicacions Forestals (CREAF)

MEETING ROOM 114, August 18, 2025, 2:00 PM - 5:00 PM

European beech (*Fagus sylvatica*) exhibits a broad distribution across Europe and has undergone local adaptation in many populations, enabling its persistence across diverse climatic conditions. We analysed eighteen Catalan populations using landscape genomics. We uncovered weak but structured genetic differentiation, revealing three main genetic provenances. Leveraging Genotype-Environment Association (GEA) methods, we also examined adaptive potential, identifying linear (LFMM, BayPass, RDA) and non-linear (Gradient Forests) relationships between allele frequencies and environmental variables. We identified numerous Single Nucleotide Polymorphisms (SNPs) correlated with environmental gradients, with an over-representation of gene classes associated with drought and heat stress responses. This suggests that genes regulating key physiological processes are involved in climate adaptation. By applying Gradient Forest, we further mapped allelic turnover across the region and delineated three distinct genetic zones. Furthermore, we projected future genetic offset (2061–2080) under all the climate scenarios available for this period, pinpointing regions at heightened risk of maladaptation and

reduced fitness. Due to the greater climate shift predicted in the Pyrenees, offset values were also higher there than in lower latitude forests, and specifically we observed the highest offsets in transition areas between valleys and ridges. We also calculated the slope of the genetic offset (Slope = Genetic offset / Environmental offset), obtaining a normalized offset that let us compare populations identifying the ones that are more preadapted to their future climate. This index also allowed us to recognize which populations are the more idoneous for a translocation experiment in a Pyrenean population, being those the ones more preadapted and with a lower offset to the future climate of the receiving population. Our results highlight the drought-temperature gradient as the primary driver of allele frequency shifts, alongside an isolation-by-distance pattern shaped by geographic distribution. These results underscore the importance of considering standing genetic variation in conservation and forest management strategies to mitigate the adverse effects of climate change, which threatens global biodiversity and may lead to local extinctions near the species' drought tolerance limit.

Using Landscape Genomics to Predict Climate Change Vulnerability in a Large Mammal Grazer

Tengstedt A¹, Tanderup S¹, Hansen M¹

¹Department of Biology, Aarhus University

MEETING ROOM 114, August 19, 2025, 11:00 AM - 1:00 PM

Understanding how species respond to rapid environmental change is essential for effective conservation. Yet, for highly mobile, wide-ranging species inhabiting heterogeneous landscapes, identifying populations most vulnerable to climate change remains a major challenge. Here, I present the methodological framework and preliminary results from an ongoing landscape genomics study of caribou (*Rangifer tarandus*), a keystone Arctic herbivore exhibiting pronounced ecological diversity and experiencing population declines in many regions. The project integrates whole-genome sequencing data from approximately 350 individuals across North America, Greenland, and Eurasia with spatially explicit environmental variables to evaluate local adaptation and predict future genomic vulnerability.

Key components include: (i) genotype–environment association analyses to identify loci involved in local adaptation; (ii) genomic offset analysis to predict populations at risk of maladaptation; and (iii) genomics-informed species distribution models (SDMs), which combine environmental predictors with adaptive genomic data to improve projections of range shifts and population persistence under climate change.

By aligning genomic variation with ecological gradients and projecting potential adaptive mismatches under future scenarios, this approach aims to bridge the gap between evolutionary insight and practical conservation management. I highlight how genomic insights may guide assisted gene flow and adaptive management in caribou populations.

POSTER SESSION 3 - **P03.056**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Convergent or repeated evolution—the independent evolution of similar phenotypes, ecological strategies, and molecular pathways—provides an opportunity to investigate the predictability of evolution. Previous research has shown that gene reuse in adaptation decreases as divergence between lineages increases, yet the extent of genomic convergence and how it scales with genetic divergence remains unclear at deeper evolutionary timescales. We address this gap by exploring the genetic basis of repeated adaptation to highly selective serpentine soils across ~25 million years of divergence in the plant model family Brassicaceae.

Using genome-wide selection scans, we aim to identify candidate adaptive genes in 10 Brassicaceae species by comparing serpentine-adapted populations with their non-serpentine counterparts. Serpentine soils represent a strong selective pressure due to an extremely skewed Ca/Mg ratio, high heavy metal concentrations, and a shortage of key nutrients. By compiling species-specific lists of likely adaptive genes for this environment and analyzing their overlap, we will evaluate the

extent of gene reuse and determine how it scales with evolutionary distance.

We expect that the decline in gene reuse at shallow taxonomic levels is primarily driven by limited allele sharing, where two or more populations retain the same adaptive allele through shared standing genetic variation or gene flow. However, the role of de novo mutations in shaping gene reuse remains less explored. Through a systematic analysis across species and genera, we aim to unravel the contributions of allele sharing versus de novo mutations, clarifying the mechanisms underlying repeated adaptation across increasing divergence scales.

Here we present our first results on population structure and the extent of serpentine candidate gene sharing across genera, *Cardamine*, *Odontarrhena* and *Alyssum*, suggesting a decline in gene reuse with increasing divergence time. Altogether, our study aims to contribute to a broader understanding of genomic convergence and repeatability and the factors shaping adaptive evolution in natural populations.

Evolution of a marine invertebrate in urban coastal habitats

Le Moan A¹, Daguin-Thiébaud C¹, Ruault S¹, Faria R², Butlin R³, Johannesson K⁴, Broquet T¹

¹Station Biologique de Roscoff, Sorbonne University, CNRS, Adaptation and Diversity in Marine Environments (AD2M), ²CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, InBIO Laboratório Associado, Campus de Vairão, Universidade do Porto, ³Ecology and Evolutionary Biology, School of Biosciences, University of Sheffield,, ⁴Department of Marine Sciences, Tjärnö Marine Laboratory, University of Gothenburg

POSTER SESSION 3 - P03.063, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Marine species experience severe modifications of their habitats in harbours and marinas, which differ from neighbouring natural habitats by multiple biotic and abiotic factors. Urban coastal zones therefore provide interesting situations to study the adaptation of marine species to anthropogenic habitat modifications. Here, we studied the marine gastropod *Littorina fabalis*, a species that is established in many marinas and that, in its natural habitat, presents two ecotypes established along meter-scale wave exposure gradients. We use this system to test whether responses to the anthropogenic gradient are similar to those found in nature and to look for genomic signatures of selection private to the urban environment. More precisely, we hypothesized that pre-existing adaptive genetic variation in wild population, notably at chromosomal inversions, has allowed rapid adaptation to the environmental contrasts created by human hands from inside to outside a harbour.

Methods: We sampled two transects covering populations established along a wave exposure gradient both in a natural and a harbour site located 30km apart in Western France. Around 150 snails were collected

along each transect. Whole Genome Sequencing (WGS) data was then analysed to study the signature of selection along the transects, and explore the role of chromosomal inversions for adaptation along a recently established artificial habitat shift (that was built 75 years ago).

Results: We found that the genomic landscape of differentiation between sheltered and exposed areas was nearly identical when comparing natural conditions to artificial settings (from the inside to the outside of a marina). Most genetic differentiation clustered within the 15 already described chromosomal inversion polymorphism. However, the change in frequency of the inversion's arrangement were much more abrupt in the harbour site, with much of the genetic variants differentially fixed over just a few meters at the entrance of the harbour (a pattern never observed so far in natural populations).

Conclusion: These results suggest that inversions responses to selection are stronger in harbour. The implication of these results to our understanding of the evolutionary responses to rapid anthropogenic changes will be discussed.

Fluctuation of population abundance over decade in one amphibian assemblage

Jovanović B¹, Crnobrnja-Isailović J^{1,2}

¹Institute for Biological Research “Siniša Stanković”–National Institute of the Republic of Serbia, University of Belgrade, ²Faculty of Sciences and Mathematics, University of Niš

POSTER SESSION 3 - **P03.057**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Amphibians are the most endangered vertebrates. Evidence on their habitat deterioration and loss suggests future population declines and critical challenges in maintaining species' genetic diversity. Long-term monitoring of local amphibian populations provides essential data for understanding their microevolutionary dynamics, including impact of genetic drift and adaptive responses to environmental stressors. Neglecting monitoring of common species might result in many silent local extinctions and in loss of information how population bottlenecks impact on evolutionary potential. Population size can be negatively influenced by climate change, particularly affecting early spring breeders. We used data on population abundance of three syntopic anuran species, collected over the years, to recognize possible loss of genetic diversity.

Materials and methods: Starting from 2011, we monitored three anuran species (*Bufo bufo*, *Rana dalmatina* and *Pelophylax esculentus* complex – PEC) in a local pond. Annual fluctuations in individual counts (N) were recorded for *B. bufo* and PEC, while for *R. dalmatina* we used egg clutches counts instead. For early breeders (*B. bufo*, *R. dalmatina*) reproductive timing was recorded. The COVID-19 interruption in 2020 necessitated predictive approximation based on the mean values from other years for reproductive season endpoints. Kendall Tau correlations were implemented to check if the parameters have trends across the years. Effective population size (N_e) and N_e/N ratios were calculated for *B. bufo*, as quick estimation of possible genetic variability loss. We applied LassoCV regression with 5-way cross-validation (23 variables) to describe what impacts on the length of reproductive season of this *B. bufo* local population.

Results: All three species exhibited annual fluctuations of population abundance, PEC

being the least variable in numbers; Kendall Tau showed no trends over years. *B. bufo* showed a constantly low female count (4–44 males per female), N_e values from 23 to 548 and N_e/N ratios from 0.09 to 0.71. Optimum alpha value for LassoCV was 0.069921482. Time needed for the number of males to drop from maximum to 0 had the greatest positive impact on duration of reproductive season (coefficient = 7.32). Time males needed to gather from the few to the maximum numbers had high positive impact (coefficient = 2.42). Time females spent in the reproductive pond had moderate positive impact (coefficient = 1.60). Time males spent there after females' departure had low positive impact (coefficient = 1.01). Difference between the date of maximum female and maximum male numbers had very low positive impact (coefficient = 0.04). Number of males had very low negative impact (coefficient = -0.001).

Conclusions: In local populations of three anuran species only fluctuations in numbers were detected. The male-biased *B. bufo* population risks allelic loss (accelerating genetic drift and inbreeding) and reduction of adaptive potential. N_e and N_e/N were typical for amphibians, with N_e/N being critically low in 2017 (0.09), indicating bottleneck. Males drive the reproductive season in *B. bufo* local population as they come first and stay after females, sometimes for a long period. Males would reach maximum numbers up to eight days later than females. Unexpectedly, start day of reproductive season didn't have any impact on the duration of reproductive season. The stable PEC population abundance suggests maintenance of genetic diversity, what buffers against environmental stochasticity. Species with stronger population fluctuations face possibility of genetic diversity loss.

How the common evening brown butterfly conquered the world

Pham Nhat T¹, Oostra V², Walczak U¹, Lohman D³, Molleman F¹

¹Adam Mickiewicz University, ²School of Biological and Behavioural Sciences, Queen Mary University of London, ³Department of Biology, City College of New York

POSTER SESSION 3 - P03.065, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Species capable of colonizing a wide range of habitats can become widespread and then encounter various environments, to which populations may evolve local adaptations. The common evening brown butterfly, *Melantis leda* (Lepidoptera: Nymphalidae), is found in almost all tropical and subtropical regions of the Old World, using forests and wooded savannah. We here aim to 1) reconstruct its global phylogeography, 2) determine population structure, and 3) infer the demographic history of populations in various regions.

Materials and methods: To cover the wide distributional range of *M. leda*, we collected DNA samples from 21 countries across three realms: Afrotropics, Indomalaya, and Australasia. We first created a reference genome and then used Illumina short-read

whole genome sequencing for 5 – 10 samples for each location at 20x coverage. We then mapped these sequences to the reference genome to identify single-nucleotide polymorphisms (SNPs). We used SNPs from the nuclear genomes to reconstruct the global phylogeography and gene flow among populations. We then estimated historical variation through time in effective population size for each population.

Results: Our results suggest that the common evening brown originated in mainland Asia, from which it colonized Australasia and, more recently, Africa. These results will provide a basis for elucidating the role of climatic variation in range expansion and population size, as well as tracing the footprints of adaptation to climate and habitat in the genome.

Local Adaptation in Baltic Cod? Insights from Early Development

Garate Olaizola M¹, Hodzic Vázquez A¹, Larsson Åberg V¹, Fröjd J², Bengström U⁴, Heimbrand Y⁴, Nissling A¹, Behrens J³, Laurila A¹

¹Uppsala University, ²Stockholm University, ³DTU Aqua National Institute of Natural Resources, ⁴SLU Swedish University of Agricultural Sciences

POSTER SESSION 3 - P03.058, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Atlantic cod (*Gadus morhua*) lay pelagic eggs that must be buoyant to develop. Baltic cod, phenotypically and genetically distinct from Atlantic cod, are uniquely adapted to the brackish Baltic Sea. Eggs from the eastern Baltic stock are buoyant at >14-15 psu, salinities found only in the south and central Baltic Proper, their historical spawning grounds.

However, laboratory experiments have shown that some Baltic cod eggs can develop at salinities as low as 7 psu, with a high survival rate at 9 psu. This environment exists in the northern Baltic Proper, in the Åland Sea, where cod are large, healthy, and in breeding condition. Yet, eggs from both northern and southern populations are negatively buoyant at these salinities, raising the questions: i) are northern cod better adapted to low salinity and ii) have they developed demersal spawning?

This study examined whether the northern population is better adapted to northern conditions than the southern population. We assessed larval survival and neutral

buoyancy after incubation at 17 psu (control), 9 psu, and 7 psu, expecting northern cod to outperform southern cod showing higher survival at low salinity and more buoyant larvae. Additionally, we tested whether Baltic cod eggs hatch from sediment.

Results show a decrease in survival rate at the lowest salinity treatment, but equally between the two populations. Neutral buoyancy differs between the salinity treatments but not between the populations, suggesting that larvae from both populations show similar physiological responses to the salinity decrease. Interestingly, northern eggs hatched from sediment, but so did southern eggs, without differences from the control (non-sediment) treatment. These results do not support the hypothesis of local adaptation to the northern Baltic environment and thereby a divergence between the two populations, but do not discard the possibility of cod being able to reproduce outside what is considered the historical spawning ground.

omniCADD: prediction variant deleteriousness beyond model organisms

Höglund J^{1,2}, Hu S², Derks M², Dalén L¹, Bosse M^{2,3}

¹Centre for Palaeogenetics, Dept. of Zoology, Stockholm University, ²Dept. of Animal Breeding and Genomics, Wageningen University & Research, ³Section Ecology & Evolution, Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit

POSTER SESSION 3 - **P03.060**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Many animal populations across the globe are currently experiencing significant declines due to environmental, ecological, and human-induced pressures. As populations decrease in size, their genetic health becomes increasingly vulnerable. Smaller population sizes are particularly susceptible to inbreeding, which can elevate the prevalence of deleterious alleles. This loss of genetic diversity reduces a population's ability to adapt to environmental changes, resist diseases, and endure long-term, ultimately increasing the risk of extinction. The genetic implications play a vital role in conservation biology and highlight the necessity to enhance our understanding and monitoring of the genomic health of endangered species. Genomic studies often focus on species with extensive genomic resources, known as model organisms, but many declining species are non-model organisms for which such resources are scarce. Therefore, developing reliable methods for assessing genetic health across a wide variety of species is essential.

Materials and Methods: To address the need for broader genomic monitoring tools, we sought to develop a predictive model capable of identifying potentially harmful genetic variants in both model and non-model organisms. Building upon earlier frameworks (Combined Annotation Dependent Depletion; CADD) that assessed variant deleteriousness within a single species, we aimed to create a more flexible and widely applicable approach. Our initial work focused on domesticated pigs (*Sus scrofa*), for which extensive genomic data are available. Using deep sequencing data from a diverse cohort of pigs, we trained a machine learning model to distinguish between benign and deleterious mutations based on a variety of genomic features. These features included conservation scores, variant effect predictions, and amino acid substitution scores.

The next phase of our study involves testing the model's transferability by applying the same methodology to wild boars (*Sus scrofa*),

functioning as the wild equivalent of domesticated pigs. This comparison will help us evaluate how well a model trained on domesticated animals performs when applied to genetically related but ecologically distinct populations. If successful, the methodology could be extended to truly non-model organisms, increasing its utility in global conservation efforts.

Results: Our preliminary model trained on domesticated pig genomes demonstrated equal accuracy in predicting deleterious variants when evaluated against the previously developed pig-specific model pCADD. The model was able to effectively differentiate between likely harmful and neutral mutations, offering a valuable tool for assessing the genetic health of pig populations. We are currently in the process of retraining the model using genomic data from wild boars, applying the same feature set and machine learning algorithms. The model can be run on species with high(er) resolution data, with the adaptation to new genomes ongoing. By directly comparing the performance of both models, we aim to assess the impact of ecological and evolutionary differences on model generalizability.

Conclusions: The development of predictive models for identifying deleterious genetic variation represents a promising direction in conservation genomics. By extending this approach beyond well-studied model species, we can improve our ability to monitor and manage the genetic health of endangered or vulnerable populations. This, in turn, may allow for more informed conservation strategies, including genetic rescue or habitat management interventions. Ultimately, our work contributes to a growing effort to integrate genomic data into conservation decision-making, to prevent further biodiversity loss, and to better understand the genetic underpinnings of species decline and extinction.

The link between Doubly Uniparental Inheritance (DUI) of mtDNA and sex determination in marine mussels: a unique case of sexual system evolution from dioecy to trioecy

Oyarzún P¹, Valdés J¹, Breton S²

¹Andrés Bello University, ²Université de Montréal

POSTER SESSION 3 - **P03.066**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Mitochondrial DNA (mtDNA) inheritance in most eukaryotes follows strict maternal transmission, where the mitochondrial genome is passed exclusively from mothers to offspring. However, certain taxonomic groups, such as marine and freshwater mussels, exhibit an atypical mechanism known as doubly uniparental inheritance (DUI). In this system, males inherit mtDNA from both parents, while females inherit only maternal mtDNA, resulting in the coexistence of two distinct mitochondrial lineages (M and F-type) within a species. The M-type mitogenome, paternally transmitted and predominantly found in males, and the F-type mitogenome, maternally transmitted and dominant in females, lead to heteroplasmy in males and homoplasmy in females. In DUI species, M- and F-type mitogenomes show significant genetic divergence (up to 40%).

The evolutionary role of DUI remains debated, but recent hypotheses suggest its involvement in sex determination. Studying mussel species with diverse reproductive strategies provides a unique opportunity to explore the potential link between DUI and sexual differentiation. Here, we investigate mtDNA inheritance and sexual system evolution in two closely related marine mussels with contrasting reproductive strategies: the trioecious *Semimytilus patagonicus* (coexisting females, males, and simultaneous hermaphrodites) and the dioecious *Perumytilus purpuratus* (separate sexes in a 1:1 ratio, with rare intersex individuals).

Materials and Methods: Mitochondrial DNA was sequenced from gonadal tissue of wild-caught hermaphroditic and unisexual *S. patagonicus*, and unisexual and intersex *P. purpuratus* specimens using the E.Z.N.A.® Tissue DNA Kit. Libraries were prepared (TruSeq Nano) and sequenced (Illumina NovaSeq, 151 bp paired-end), yielding 30 Gb of

data. After quality trimming (Q20, removal of reads <40 bp), reads were mapped to M/F-type reference mitogenomes (CLC Genomics Workbench v.24.0.1) under stringent parameters. Species-specific primers were designed for validation.

Results. We confirmed DUI in both species. In *S. patagonicus*, hermaphrodites exhibited heteroplasmy in male gonadal tissues (M+F mitogenomes), while female tissues were homoplasmic (F-type only). Unisexual individuals (males/females) lacked DUI: males carried only M-type, and females only F-type. Comparative mitogenomic analysis revealed structural differences: male M-type genomes had repetitive sequences (particularly near rRNA genes) and deletions in ND2, ND6, ND4, CYTB, and COX3.

In *P. purpuratus*, dioecious individuals followed classic DUI (heteroplasmic males, homoplasmic females), but intersex individuals lost DUI, with male gonadal tissues harboring only M-type and female tissues only F-type. Intersex individuals also showed mitogenome synteny differences.

Conclusions. Our results demonstrate an association between doubly uniparental inheritance (DUI) and sexual differentiation, particularly in hermaphroditic and intersex individuals. The structural reorganization of rRNA genes and accumulation of repetitive elements in M-type mitogenomes suggest their potential functional involvement in mitochondrial gene regulation during sex determination. DUI appears to facilitate sexual plasticity in these organisms. This study provides critical insights into mitochondrial inheritance's role in bivalve sexual differentiation and advances understanding of evolutionary mechanisms behind sexual plasticity in organisms with atypical mtDNA inheritance—a unique case in Animalia. The role of developmental plasticity in the resilience of spionid populations

Edwards L¹, Smallegange I¹

¹Newcastle University

POSTER SESSION 3 - **P03.064**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Alongside mutation, plasticity is a key driver of phenotypic diversity within populations. It creates diversity by producing different phenotypes from a single genotype, depending on the environmental cues an individual receives. Producing phenotypes through adaptive plasticity means that individuals may be able to match their phenotype as close as possible to the environmental optimum, maximising fitness. Such phenotype matching often explains why some species are particularly effective at invading novel environments, whilst others are not. At the population level, plasticity can mitigate selection by buffering individuals against selection. This has significant consequences on evolution, since plastic populations will possess more phenotype variance which can be selected on, in addition to having more cryptic genetic variation than non-plastic populations. However, aside from being used to explain the prevalence of plasticity among invasive species, the buffering effects of plasticity on populations have rarely been tested outside of a lab-setting. Such a research gap brings

into question whether we can observe any tangible differences between plastic and non-plastic species in their population persistence or extirpation. To examine this, we use a timeseries of spionid species abundance across the Wadden Sea, since it is both a long-term (15 year) and high spatial-resolution dataset. Using this system, we ask whether populations of plastic species are more resilient to environmental change than non-plastic species, before going on to examine whether plastic species perform better in highly varied environments than non-plastic species. We find that plastic species experience less variance in population size than non-plastic species, indicating significant buffering and suggesting that these plastic species may have a greater capacity to adapt plastically and evolutionarily to changes in their environment. We conclude by discussing the implications of this for evolution amongst spionid populations, and potential uses for this system in examining eco-phenotypic feedbacks.

Where have all the flowers gone? What could we start learning about possible evolutionary patterns from multi-year study of population dynamic of sexual and vegetative reproduction in clonal *Iris pumila* natural population in Deliblato Sand

Tarasjev A¹, Barišić Klisarić N¹, Avramov S¹, Živković U¹, Miljković D¹

¹Institute For Biological Research "Siniša Stanković", University Of Belgrade

POSTER SESSION 3 - **P03.062**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

To forecast changes in natural populations we must consider multiple factors including environmental ones, and identify components of our predictive framework that are most in need of improvement. These issues can be approached through the empirical analysis of natural populations of existing model systems.

Such a system that has been studied for the last 35 years is the dwarf bearded iris, *Iris pumila* L. (Iridaceae), a small monocot that occurs in the lowlands of central and eastern Europe. Being a perennial clonal plant that spreads vegetatively through underground rhizomes („phalanx“ strategy of spread), *I. pumila* also possesses hermaphroditic, entomophilous flowers, and is a strictly outcrossing species. One of the most astonishing features of *I. pumila* is its huge flower color polymorphism that exist in each population, and studies explaining this kind of phenomenon are scarce. Flower color polymorphism and species population dynamic are closely connected and, in perennial plants with both vegetative and sexual reproduction, all those components should be jointly considered in selection analyses, as well as their spatial and temporal variability patterns.

In *I. pumila* natural population situated in Deliblato Sand Natural Reserve (40 km northeast of Belgrade, Serbia) we placed twenty-five 12 x 12 m grids and ten 7 x 7 m grids, leading to total of 4090 square meters covered. During 2013-15 flowering seasons we recorded occurrence of all flowers in each of 4090 selected square meters by means of digital color photography. Since 2021, data collection was considerably enhanced by utilization of DJI Mavic Pro drone with Hasselblad L1D-20c aerial camera. This left enough time for simultaneous sample collection for reflectance UV enhanced spectroscopy (since 2021), as well as for HPLC and microsatellite analyses (since 2024), preliminary results of which would be separately presented at ESEB 2025.

Preliminary analysis of ten 7 x 7 m grids presented in this work revealed huge differences between flowering seasons in flowering phenology. While differences between flowering onsets and peaks in different flowering seasons can be traced down to different environmental conditions, reasons and mechanisms for observed constant decline in number of flowers (from several thousands to the only couple of hundred flowers in the subsample) is a component of our predictive framework that is in the need of further investigation. To begin with, preliminary analyses clearly indicated switches between reproductive modes since decline was mostly due to lesser percentage of individual ramets that produced flowers, compared to much smaller decline as a result of reduction in number of *I. pumila* individual plants.

Those analyses should be expanded to the whole sample and further combined with results of future flower color and genetic analyses, since interplay between sexual and vegetative reproduction in self-incompatible species crucially depends on spatial genetic composition. Those lines of research can then have impact on our understanding of possible evolutionary changes in natural populations of *I. pumila*.

Divergence time and environmental similarity shape the repeatability of morphological evolution in stick and leaf insects.

Boisseau R¹, Bradler S², Emlen D³

¹University Of Lausanne, ²University of Göttingen, ³University of Montana

MEETING ROOM 129+130, August 22, 2025, 10:30 AM - 12:30 PM

The observation of repeatability in phenotypic evolution across taxa suggests that, at least sometimes, evolution may be forecasted. Yet it is still unclear what factors determine the level of repeatability (and, by extension, predictability) of evolutionary outcomes and trajectories. If independent lineages are subjected to the same environmental challenges, what factors influence how often they evolve the same phenotypes? When does repeatability break down?

One possibility is the genetic distance between lineages: closely related lineages will share more standing genetic variation, genetic background and developmental mechanisms and are therefore expected to respond in a more analogous way to similar selective regimes. Another possibility is the actual degree of environmental similarity and therefore the extent to which the selective regimes are similar between independent lineages occupying qualitatively and seemingly identical environmental niches.

We tested the effects of these two factors using stick and leaf insects (order Phasmatodea) lineages that repeatedly transitioned to similar habitats. Phasmids are renowned for their extraordinary morphological diversity associated with camouflage, ranging from elongated branch

mimics to wide and flattened leaf mimics. We used morphological measurements for 212 species spanning all major clades to reconstruct a multidimensional morphospace which, in combination with a robust phylogenetic reconstruction, was used to show the repeated evolution of many ecomorphs in the group. We show that when transitioning to the same habitat, stick insect lineages that are more closely related and experiencing more similar environmental conditions end up displaying more similar morphologies at present. More closely related lineages also display more parallel trajectories on the morphospace following the transition.

Our work sheds light on two critical factors that influence the level of predictability of phenotypic evolution. Our findings directly evidence both the contingent and deterministic nature of evolution: independent lineages evolve in more analogous ways when submitted to more similar environmental pressures (determinism) and when they are less genetically divergent (contingency). We show that the extent of repeatability decreases at a relatively constant rate across more than 100 My of divergence, suggesting that even the magnitude of contingency can be predictable, given sufficient spans of time.

Jointly forecasting adaptive evolution and demography: refining tools and semantics.

Bonnet T¹, Van de Walle J^{2,3}, Garnier J⁴, Jenouvrier S²

MEETING ROOM 129+130, August 22, 2025, 10:30 AM - 12:30 PM

Forecasting evolution in natural populations is an important task, and one that often benefits from a complementary demographic perspective. Indeed, accurately predicting evolution in stage-structured populations requires accounting for demographic structure. Further, understanding the demographic consequences of evolution is a major goal in the context of unprecedented environmental changes. Finally, demography can also feedback on evolutionary processes, which may affect forecasts.

To help with these goals we developed a new Evo-Demo Hyperstate Matrix Population Model (EvoDemo-Hyper MPM) that incorporates the two-sex genetic inheritance of quantitative traits, enabling fast computation of projected evolutionary and demographic dynamics under dynamic environments. EvoDemo-Hyper MPM overcomes some limitations of previous matrix Evo-Demo models, in particular in relation to the representation of genetic

inheritance. EvoDemo-Hyper MPM matches outcomes from individual-based simulations and analytical approximations under simple biological conditions, but is much faster than individual-based simulations and more flexible than analytical approximations. I will illustrate the method with empirical evolution-demography forecasts for a wild population of wandering albatrosses experiencing effects from climate change.

While developing the model we identified major semantic differences between fields, which may explain misunderstandings between researchers from different fields working on the same question. I will present the different points of view and show that they produce equivalent results, but express them on different scales. Ultimately, progress on forecasting evolution requires integrative approaches, and with it for researchers from different traditions to understand each other.

Quantitative prediction of population mean fitness evolution: intra- and inter-sexual genetic (co)variances measure the expected amount of adaptive change to survival and reproduction in the face of sexual conflict and competition

Wolak M¹, Brown O¹

¹Auburn University

MEETING ROOM 129+130, August 22, 2025, 10:30 AM - 12:30 PM

Predicting how fitness evolves in a population is a central objective in evolutionary biology and population ecology. Total change in fitness can be formalized using the Price Equation to partition population mean fitness change due to natural selection from other evolutionary and environmental causes. However, most studies to date have invoked Fisher's Fundamental Theorem of Natural Selection to predict the rate of population mean fitness change due to natural selection as a function of the additive genetic variance in fitness, thereby leaving out abiotic or biotic changes in the environment, such as competition, and implicitly assuming hard selection. Despite a long history of theoretical development, there has been comparatively little empirical testing of either the Price Equation or Fisher's Fundamental Theorem to make quantitative predictions of future changes in population mean fitness. We used experimentally manipulated, replicate populations of seed beetles (*Callosobruchus maculatus*) to empirically parameterize the Price Equation and Fisher's Fundamental Theorem of Natural Selection and evaluate our ability to use them to make prospective predictions for the rate of change in population mean fitness.

In each replicate we applied a complex breeding design over multiple generations

coupled with individual survival and competitive mating success assays to enable fitting a quantitative genetic model that accounts for sex-specific direct and indirect (i.e., competitive effects) additive genetic variances and covariances for lifetime survival and reproductive success. These analyses revealed the magnitude by which intralocus sexual conflict, estimated by the cross-sex additive genetic covariance, creates a gender load that reduces the total additive genetic variance for fitness and impedes the rate of evolution in population mean fitness. We also estimated relatively small genetic variances for conspecific competitive effects, thereby quantifying the potential for this source of environmental deterioration to reduce the adaptive potential of population mean fitness, as described by the Price Equation. By decomposing quantitative predictions for change to mean population fitness into adaptive change, realized by the systematic differences in sex-specific strategies to maximize fitness, and changes in soft selection, measured by the evolutionary potential of competitive interactions, we demonstrate the importance of quantifying key components in accurate evolutionary prediction that have heretofore been neglected.

The use of multi-response models to improve inferences about natural selection

Dobson S¹, Pick J¹, Mittell E¹, Walling C¹

¹University Of Edinburgh, Institute of Evolution and Ecology

MEETING ROOM 129+130, August 22, 2025, 10:30 AM - 12:30 PM

Understanding the process of natural selection is a key goal in ecology and evolution, and accurate estimates of selection are essential if we are to hope to correctly predict and forecast how wild populations will evolve over time. Lande and Arnold proposed a simple linear regression-based approach to estimate selection which has allowed ecologists to measure selection on a range of phenotypic traits and revolutionized the study of evolutionary ecology. However, despite the benefits of the Lande-Arnold approach, and its widespread use for estimating selection in wild populations, issues around interpreting causality from these estimates remain. Furthermore, the potential importance of hard and soft selection, including how they can bias selection gradient estimates depending on how fitness has been standardized, remains relatively unexplored. Here we show how, when fitness and traits have been measured repeatedly across

individuals and common environments, selection gradients can be decomposed into their causal components and that this decomposition can help reveal if estimates of selection are consistent with causality and distinguish and correct for soft selection. We also show how, without additional data, multi-response models can be used achieve this decomposition and thus improve our estimates of selection in wild populations. We demonstrate these methods using an empirical example in a wild population of red deer and highlight the difference this makes to our estimates of selection, and our understanding of them, compared to those estimated using the Lande-Arnold approach. Given the relative ease with which multi-response models can be applied, we hope that our illustration of this approach will allow application across a range of systems and thus improvement of our estimates and ultimately our understanding of selection and evolutionary processes.

S25 - Gene Content Across Genomes: Models and Genomic Data

A high-quality genome for *Pagodroma nivea* facilitates understanding the evolution of highly adapted 'tube-nosed' (Procellariiformes) seabirds

Rix A¹, McClymont E¹, Hoelzel R¹

¹Durham University

POSTER SESSION 3 - **P03.073**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

To enable more informative comparative genomics, more high-quality genomic resources are needed. We present the most contiguous genome generated for a petrel, albatross, or shearwater (order Procellariiformes), generated through PacBio HiFi sequencing complemented with short-read and Hi-C analyses. We sequenced one of the southernmost breeding species of birds from this order, the snow petrel (*Pagodroma nivea*). Snow petrels are endemic to the Antarctic mainland and surrounding sub-Antarctic islands and widely distributed in that habitat. They are one of only three species that have been seen at the south pole. Like all Procellariiformes, they have a tubular nasal passage that enhances olfaction, and they drink seawater, necessitating salt regulation, aided by their nasal anatomy. Species in this group forage over a broad oceanic range, facilitated by their enhanced olfaction which likely aids both finding prey and navigating back to their home colonies. We are interested in the genomic adaptations associated with these enhanced faculties. Using our newly generated genome and after annotating available Procellariiformes and

other seabird genomes, we compared gene family expansion and contractions. For example, Procellariiformes and penguins have 30 significantly contracted genes compared to other seabirds. Furthermore, select genes involved in esterification, osmolytes, ion transport, and the family of olfactory receptor loci were investigated. We also compared our new snow petrel genome to genome assemblies for other bird species from the Austrodyptornithes clade. With respect to patterns of genome structure, while the longest four chromosomes were highly conserved, rearrangements were more common on the smaller chromosomes. Through our long-read generated genome, we were also able to examine duplications in mtDNA that are common in birds, but difficult to detect without long read sequencing. The generation of new high-quality genomes enables comparative genomics and allows discoveries into what makes orders unique. We will discuss what our chromosome-level genome together with comparative genomic analyses tells us about the evolution of this highly adapted order of seabirds.

A phylogeny aware analysis of function for the biodiversity genomics era

Diwan G¹, Natsidis P², Gonzalez-Sanchez J¹, Colbourne J³, Telford M², Russell R¹

¹Bioquant, University Of Heidelberg, ²University College London, ³University of Birmingham

POSTER SESSION 3 - P03.068, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

A fundamental question in biology is: when did a certain function originate? Was it recent or existent millions of years ago in the ancestors of extant species? We are currently in an era where the burgeoning amount of whole genomic data and advancements in annotation methods has given rise to an unprecedented number of complete, well-annotated proteomes from across the tree of life. It is thus possible to leverage the data available in public databases and reconstruct the detailed evolutionary history of genes, pathways and more broadly biological functions. In this study, we used the homolog and ortholog information of ~4.5 million proteins from 508 species across the tree of life and traced the emergence and evolutionary history of every gene. Next, we grouped genes by their function (GO terms/protein domain architecture) or membership to biological pathways (KEGG/Reactome) and traced the

emergence and evolutionary histories of these broader functional entities.

We found that the largest founder events of biological entities were in eukaryotes, more specifically in vertebrates, angiosperms, and slime molds. Upon inspection of GO terms and KEGG/Reactome pathways enriched at each node in the tree, we observed characteristic adaptations emerging. We also show parallel independent evolution of key genes and functions across clades with large transitions such as aquatic to terrestrial and unicellularity to multicellularity. Overall, our work is the first to elucidate the detailed evolutionary histories of biological functions using genomic annotations, which can be explored on a web application. We envision this work will be useful to a wide variety of scientists interested in the molecular history of life on earth.

Antibiotic Resistance Prediction in *Staphylococcus aureus* Using Gene Content Outperforms SNV-Based Approaches

Fistarol B¹, Diniz Brandao Gervasio J¹, Szollosi G¹

¹Okinawa Institute Of Science And Technology

POSTER SESSION 3 - **P03.079**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Antibiotic resistance is a critical global health issue. Advances in genome sequencing and computational methods have enabled rapid prediction of bacterial resistance profiles. Although single nucleotide variant (SNV)-based models are often used, they may perform poorly when generalizing to novel strains due to population structure effects. Models based on whole genome sequences or specific resistance genes are also widely used, however, obtaining complete assemblies or resistance gene profiles can be challenging in rapid sequencing approaches like metagenomic shotgun sequencing from patient samples. Such methods typically generate fragmented data, providing only a broad view of the genome. In this context, clustering homologous genes and using their counts emerges as a practical alternative for resistance prediction. Here, we show that gene content can predict antibiotic resistance in *Staphylococcus aureus* and outperforms SNV-based approaches when generalizing across phylogenetic clades.

Materials and Methods: *S. aureus* genomes and antibiotic resistance phenotypes for six drugs were downloaded from the BV-BRC database, with sample sizes varying by drug (842-2681 strains). Protein-coding genes were predicted from genomes using Prodigal and clustered with CD-HIT at 80% identity. Cluster assignments were parsed into a matrix representing the number of genes from each cluster per strain. XGBoost classifiers were trained to predict resistance using gene cluster counts with an 80/20 train-test split. Clusters were iteratively removed based on XGBoost's importance by weight, retraining the model each time until the F1-score (harmonic mean between precision and recall) fell below 0.5. To investigate phylogenetic relationships among the strains, IQTree was employed to construct trees using (1) binary gene content matrices (0/1 indicating cluster absence/presence) and (2) concatenated alignments of 313 single copy core genes (present in $\geq 99\%$ of strains). Core gene

alignments were used to train additional XGBoost models, with each nucleotide encoded as an integer. To simulate generalization to novel strains, models were also trained and tested on different clades based on phylogenetic trees from core sequences.

Results: Models using gene cluster counts achieved high predictive performance, with F1-scores ranging from 0.934 to 0.995 across antibiotics. Feature importance analysis showed that resistance prediction relies on a broad set of gene clusters: contrary to our expectation that predictive scores would decay after removing few clusters, F1-scores remained above 0.5 even after removing over 30% of the most important features. On average, performance remains robust ($F1 \geq 0.8$) after removing 1232 ± 606 clusters, indicating that prediction is driven by distributed genetic signals. Phylogenetic trees based on both gene presence/absence and core gene sequences showed partial clustering of resistant and susceptible strains. Trees from core sequences also allowed identification of clades for phylogeny-aware model evaluation. SNV-based models achieved good F1-scores under random splits but showed substantial drops when evaluated on unseen clades, performing not better than random predictions. Surprisingly, gene content models maintained higher performance across the same unseen clades, with average F1-score of 0.9 across all antibiotics in all tested clades.

Conclusion: Homologous gene cluster counts can accurately predict antibiotic resistance in *S. aureus* and outperform SNV-based models in generalizing to novel phylogenetic lineages. Resistance prediction is supported by a distributed set of gene features rather than a few major determinants. Gene content-based approaches offer a robust strategy for predicting resistance, motivating future investigation of biological relationships between antibiotic resistance and a broad set of gene clusters.

Archaeorhizomycetes, a diverse group of ancient root endophytes

Sanchez-Garcia M^{1,2}, **Nielsen K**¹, Tuovinen Nogerius V¹, Cisse O³, James T⁴, Scofield D¹, Spatafora J⁵, Stajich J⁶, Rosling A¹

¹Uppsala University, ²Swedish University of Agricultural Sciences, ³National Human Genome Research Institute, NIH, ⁴University of Michigan, ⁵Oregon State University, ⁶University of California, Riverside

POSTER SESSION 3 - **P03.088**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: Our understanding of evolution is primarily informed by a few lineages, which comprise a tiny fraction of the entire tree of life. For example, it is estimated that only 1-5% of fungal diversity is currently known.

Archaeorhizomycetes (Taphrinomycotina, Ascomycota) is an understudied class of soil fungi that exemplify the difficulty of studying the diversity and evolution of most fungi, which lack macroscopic structures and are recalcitrant to culturing. Archaeorhizomycetes is a diverse and globally distributed class, with unknown ecological roles and life cycles and no observed sexual structures. Archaeorhizomycetes eDNA is frequently detected in soil and often in high abundance, regularly representing the majority of fungal amplicons. Despite extensive isolation efforts over more than a decade, only four species – *Archaeorhizomyces finlayi*, *A. borealis*, *A. notokirishimae*, and *A. ryukyuensis* – are formally described and maintained in axenic cultures. However, global richness estimates suggest the class may comprise > 15000 species (1.5% dissimilarity threshold).

Phylogenetic analysis supports the placement of Archaeorhizomycetes as one of the distantly related lineages of the monophyletic subphylum Taphrinomycotina, with *Neolecta* weakly supported as its closest sister-lineage. *Neolecta* is a genus of root-associated fungi that exhibit an independent origin of complex multicellularity and fruiting-body formation among basal ascomycetes. Taphrinomycotina, which also includes fission yeast (*Schizosaccharomyces*) and lung pathogenic *Pneumocystis* yeast, constitutes an ecologically diverse group where the majority of described species are dimorphic plant pathogens that belong to the Taphrinales order. Taking into account undescribed Taphrinomycotina diversity, Archaeorhizomycetes stand out as exceptionally diverse and is likely the most species rich lineage within the subphylum.

Material and methods: We sequenced the genomes of *A. finlayi* and *A. borealis* with PacBio and reconstructed a phylogeny including all the

main subphyla of Ascomycota. We performed comparative genomics across Taphrinomycotina and inferred changes in gene family size with CAFE. With BLAST, we identified genes related to sexual reproduction and estimated the number of rDNA copies per genome.

Results: We present the genomes of *A. borealis* and *A. finlayi* and thus contribute the first genomic data for Archaeorhizomycetes, which despite its prevalence in soil, has proven recalcitrant to culturing. We confirm the placement of Archaeorhizomycetes in Taphrinomycotina as a sister lineage to *Neolecta* with strong support. For comparative genomics, we focused on genes that are known to play important roles in fungal-plant interactions, namely: small secreted proteins (SSPs), peptidases, and carbohydrate-active enzymes (CAZymes). We found that Archaeorhizomycetes have the genes needed for sexual reproduction, despite no observed sexual structures. However, the precise sexual system of Archaeorhizomycetes is difficult to address since we can only identify one MAT locus idiomorph with certainty. For biological and technical reasons, abundance of fungal biomass cannot be directly inferred from relative read abundance in metabarcoding data. For example, rDNA copy number varies extensively across the fungal kingdom. We estimate the rDNA copies per genome to be 4 in *A. finlayi* and 10 in *A. borealis*, which is relatively low compared to the ascomycete average of 50 copies. This in turn indicates that the high read abundance of Archaeorhizomycetes in soil reflects real cellular abundance.

Conclusions: We confirm the placement of Archaeorhizomycetes in Taphrinomycotina with *Neolecta* as a sister lineage. Our results from comparative genomics analysis, rDNA copy number estimates, and mating system characterization, brings us towards a better understanding of the ecology and evolution of Archaeorhizomycetes.

Comparative analysis of Genes encoding Ribosomal Proteins across Metazoa

Suresh M¹, Giacomelli M¹, Lozano Fernandez J¹

¹Faculty of Biology, University of Barcelona

POSTER SESSION 3 - **P03.087**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Protein synthesis (translation) is a necessary attribute of life as we know it. It is mediated by the translational machinery, in which ribosomes play a central role. Ribosomes are complexes of structural ribosomal RNA (rRNA) and proteins (e.g., ribosomal proteins, translation factors, tRNA synthetases) that universally share a core structure within their 2-subunits arrangement. Part of the genes encoding the translation machinery are shared as orthologues across the whole Tree of Life, and, as such, these genes have always been considered ideal as phylogenetic markers to investigate splits that happened in deep

time. However, when it comes to animals (Metazoa), a comprehensive characterisation of such genes –quantifying the number of their duplications, as well as the rate of evolution, for example– is still lacking. Here, to fill this gap, we analyse 136 gene families of translational genes across Metazoa. We present and discuss the distribution of such genes and the phylogenetic patterns across animals, as well as characterise some of their evolutionary features. This work aims to provide critical insights into the evolutionary dynamics of genes involved in translation, primarily Ribosomal Protein coding genes.

Comparative genomics provides insights into early angiosperm evolution

Bowles A¹

¹University Of Oxford

POSTER SESSION 3 - **P03.071**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Angiosperms emerged through an early evolutionary burst over 150 million years ago, leading to the two major groups, the monocots and eudicots. These comprise over 95% of flowering plant diversity, but have key differences in their morphology, ecology and life histories. Pinpointing how these two groups evolved to be so different requires a detailed reconstruction of the genomic changes during flowering plant evolution. However, the macroevolutionary trends governing flowering plant gene family repertoire remain poorly understood.

Here by analysing 273 archaeplastid genomes representing 50 flowering plant orders, we identify high rates of gene loss and

duplication in the evolutionary history of angiosperms. Monocot diversification was accompanied by a period of reductive genome evolution while the first eudicot genomes experienced modest rates of gene duplication. Orders were characterised by rampant gene loss, compensated by modest gene duplication. This suggests that angiosperms reached a core genomic diversity early in their evolutionary history, corresponding to their high morphological diversity. This work highlights the importance of loss as well as gain of function in the diversification of the most speciose plant group.

Comparative genomics provides insights into early bryophyte evolution

Bowles A¹

¹University Of Oxford

POSTER SESSION 3 - **P03.069**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Land plants originated from a streptophyte algal ancestor ~500 million years ago, marking one of the most significant events in Earth's history. On land, these ancient plants diverged into two major lineages: the monophyletic bryophytes and vascular plants. Recent findings have shown that the first bryophytes emerged through reductive evolution, implying they derive from a more complex ancestor. The main bryophyte lineages, hornworts, liverworts and mosses, display a patchwork of traits, many shared with vascular plants. This raises the question: does bryophyte trait distribution represent convergent or reductive evolution? And does this extend to their genes and genomes?

Here, I will present my work investigating gene content evolution accompanying the early diversification of bryophytes. This analysis, using sophisticated gene-tree-species-tree reconciliation methods, shows that hornworts, the first splitting lineage of bryophytes, have the largest occurrence of gene loss. Functionally, many of these lost genes are linked to the development of water conducting cells, a trait lost in hornworts. Further analysis demonstrates convergent evolution between genetic networks in vascular plants and water-conducting mosses. These analyses suggest that a patchwork of genetic mechanisms regulated early bryophyte evolution. This work is revealing the complexities of the earliest land plants, with implications for bryophyte and embryophyte trait evolution.

Convergent evolution of cosexuality in liverworts

¹University Of Zurich

POSTER SESSION 3 - P03.075, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Sex chromosomes are expected to coevolve with their respective sex, potentially disfavoring their co-occurrence as cosexuality evolves. This effect is expected to be stronger where sex chromosomes are restricted to one sex, such as in plants expressing sex in their haploid stage. We assess this hypothesis in liverworts with U/V sex chromosomes, ancestral dioicy, and several independent transitions to monoicy (cosexuality). We report the chromosome-level genome assembly of *Marchantia quadrata*, which recently evolved monoicy, and perform comparative genomic analyses

with its dioicous relative *M. polymorpha*. We find that monoicy evolved via retention of the V chromosome as a small ninth chromosome, complete loss of the U chromosome, and translocation of key U-linked genes to autosomes, among which the major sex-determining gene (*Feminizer*) acquired environmental/developmental regulation. Our findings parallel recent observations on *Ricciocarpos natans*, which evolved monoicy independently, suggesting genetic constraints that may make transitions to monoicy predictable in liverworts.

Does Metabolite Toxicity Impact Gene Order in Metabolic Operons through Selection for Robust Gene Expression?

Fernandez De Grado Q¹, Frenoy A¹

¹Université Grenoble Alpes

POSTER SESSION 3 - **P03.070**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Bacterial genomes are organized in operons, grouping multiple genes that are expressed in similar biological conditions. We study the order of genes within operons, a question that has received little attention. The specific question we ask is whether two genes catalyzing two successive reactions of a metabolic pathway are encoded in the same order within their operon than they appear within the pathway. A pioneer study has shown 15 years ago that the answer is yes for more than half of such gene pairs, and suggested a mechanism leading to a selection pressure for coding genes in this order. On the opposite, in this work we are looking for selection pressures which could explain why a significant amount of gene pairs are encoded in the invert genetic order.

For all metabolic operons of *E. coli*, we computed several features which could directly or indirectly reflect the benefit of the invert genetic order, such as essentiality of each gene, fitness defect associated with

knockout or over-expression of each gene, average expression level of the operon, potential toxicity of the intermediate metabolite between the two reactions, and conservation of the genes in their order in other organisms.

We found that fitness defect caused by knockout of the downstream gene within the pathway is significantly associated with the inverse gene order (in which this downstream gene is encoded first in the operon), suggesting that this inverse order arises from a selection pressure for strong and robust expression of the downstream gene. We postulate that in some pathways, this selection pressure could be caused by the toxicity of the intermediate metabolite, leading to a benefit in stronger and more robust expression of the gene which consumes the metabolite than the gene which produces it.

Evolution of amylase copy number variation in Nile rats and functional impact

Bueno Landau L¹, Pajic P¹, Kassem S¹, Ruhl S¹, Toh H², Gokcumen O¹

POSTER SESSION 3 - **P03.080**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The Nile rat (*Arvicanthis niloticus*) is a valuable diurnal model for studying metabolic diseases due to its human-like circadian rhythm and strong susceptibility to diet-induced diabetes, particularly on starch-rich diets. Evolutionarily, Nile rats may have lost their ancestral ability to efficiently metabolize starch, as their native diet consists primarily of fiber-rich, starch-poor vegetation. Amylase is a key enzyme for starch digestion, and its encoding gene (AMY) exhibits copy number variation (CNV) across mammals, often correlating with dietary starch consumption. In humans, AMY CNV has been associated with metabolic traits such as obesity and diabetes, and is under selection in starch-consuming populations. We hypothesized that the amylase gene cluster evolved uniquely in Nile rats as part of an adaptive response to their natural diet, with functional consequences for starch metabolism and disease susceptibility. To explore this, we employed three complementary approaches. First, we genotyped AMY CNV using droplet digital PCR (ddPCR) in 159 Nile rats and observed copy numbers ranging from 4 to 12 per diploid genome. Notably, individuals with higher AMY copy numbers were significantly more likely to develop diabetes on a high-starch diet ($p < 0.01$), suggesting a gene dosage effect on metabolic disease risk. Second,

transcriptome analyses across multiple tissues revealed that Amy2 and a recently duplicated paralog, Amy2', are specifically expressed in the pancreas, while Amy1 is expressed in the parotid salivary glands. This tissue-specific expression supports subfunctionalization of the amylase paralogs. Phylogenetic reconstruction indicated that Amy2' is a species-specific duplication within Nile rats, while Amy1 likely originated from an older duplication event preceding the divergence of rats and mice. Third, to better understand the structural evolution of the AMY locus, we generated long-read, high-accuracy sequencing data from multiple Nile rat individuals. These data enabled full haplotype reconstruction of the amylase region and revealed extensive structural rearrangements, providing a clearer view of the CNV architecture. Together, our results uncover substantial amylase CNV in Nile rats, highlight its association with starch-induced diabetes, and reveal evolutionary and functional divergence among AMY paralogs. These findings offer insight into how gene duplication and structural variation can contribute to metabolic adaptation and disease, and they establish a framework for further investigation into the evolutionary genomics of diet-related traits in this emerging model organism.

Evolutionary diversity of CXCL16-CXCR6: Convergent substitutions and recurrent gene loss in sauropsids

Salve B¹, Vijay N¹

¹IISER Bhopal

POSTER SESSION 3 - **P03.067**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: The interaction of chemokines with chemokine receptors guides immune cells to target sites, impacting immune defence efficacy. The CXCL16-CXCR6 axis is crucial for regulating CD8 tissue-resident memory T cells (TRM) persistence. CXCR6 serves as the core TRM marker gene along with CD69, ITGAE, and ITGA1. TRM cells are critical for effective immunity against pathogenic infections such as influenza. In mice, CXCR6 deficiency lowers TRM cell numbers in the lungs and depletes ILC3s in the lamina propria, impairing mucosal defence. This axis is linked to diseases like HIV/SIV, cancer, and COVID-19. The unique DRF motif of CXCR6 facilitates leukocyte adhesion by interacting with cell surface-expressed CXCL16 and plays a key role in G-protein selectivity during receptor signalling. Together, these highlight that the CXCL16-CXCR6 axis is pivotal in host immunity. Previous studies of the CXCL16-CXCR6 axis found genetic variation among species but were limited to primates and rodents.

Materials and methods: To investigate the evolutionary trajectory of CXCR6 and its ligand CXCL16, we performed a comparative genomic analysis encompassing approximately 425 vertebrate species, including fishes, amphibians, reptiles, birds, and mammals. We analysed the genome assemblies and short-read sequencing data using tools such as TOGA and BLAST to confirm gene loss. The G-protein coupling probabilities of CXCR6 were predicted using PRECOGx, while molecular dynamics (MD) simulations were employed to identify key interacting residues. To evaluate the functional implications of gene loss, we analysed publicly available single-cell transcriptomic datasets from mallard, pigeon, and chicken lungs. Furthermore, these genes' selection

signatures and convergent substitutions were analysed using Hyphy, PAML, and CSUBST.

Results: Our evolutionary trace analysis of the DRF motif found that this motif is not universal across all vertebrates. The DRF motif is restricted to mammals, turtles, and frogs, while the DRY motif, typical in other chemokine receptors, is found in snakes and lizards. Most birds exhibit the DRL motif. Furthermore, by using molecular dynamics simulations and the machine learning-based tool PREGOCx, we show that these substitutions at the DRF motif affect the receptor—Gi/o protein interaction. We establish recurrent CXCR6 gene loss in 10 out of 36 bird orders, including Galliformes and Passeriformes, Crocodilia, and Elapidae, attributed to segmental deletions and/or frame-disrupting changes. Notably, single-cell RNA sequencing of the lung shows a drop in TRM cells in species with CXCR6 loss. The reduced TRM cell abundance in species which have lost the CXCR6 gene further emphasises its importance in immune cell localisation and function. Furthermore, the concurrent loss of ITGAE, CXCL16, and CXCR6 in chickens may have altered CD8 TRM cell abundance, with implications for immunity against viral diseases and vaccines inducing CD8 TRM cells.

Conclusions: Our comparative genomic study for CXCR6 gene presence/absence establishes recurrent loss of the CXCR6 gene in sauropsid lineages via segmental deletion and/or frame-disrupting changes. Our results highlight the evolution and diversification of CXCL16-CXCR6 in sauropsids through the repeated concurrent loss of CXCL16-CXCR6 and variation at the DRF motif (DRF/DRL/DRY). Furthermore, species with CXCR6 gene loss may be targeted for therapeutic approaches to enhance TRM retention and improve vaccination outcomes.

Exploring the transcriptional landscape of environmental samples using metatranscriptomics long reads

Lafuente Sanz C¹

¹CEA -- Institut de Génomique – Genoscope

POSTER SESSION 3 - **P03.074**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Introns and splicing in eukaryotic marine organisms exhibit unique characteristics compared to other eukaryotes. In particular, splice sites in these organisms often do not adhere strictly to the GT-AG conventional rule, and we can find one or both of these terminal dinucleotides changed, resulting in what are termed non-canonical introns (NCI) (1–3).

During TARA Oceans (2009-2013), and later the TARA Pacific expedition (2016-2018) sea-water samples containing viruses, bacteria and plankton were collected (4,5), and some of them were sequenced using long-reads sequencing. These data represent a valuable resource to study non-canonical splicing in planktonic eukaryotes.

After adjusting aligning parameters to enable the detection of novel non-canonical splice sites, metatranscriptomic long reads were mapped to metagenomic data from TARA Ocean and TARA Pacific expedition, in order to extract exon-intron structures. This resulted in the identification of a variety of non-canonical introns, some of them likely corresponding to introner elements, i.e. introns derived from the insertion of transposon like sequences (6).

In total, a large number of introns were identified using several metagenomic references. After filtering and analysing them, we observed that some of them exhibited unique splice sites, revealing diverse and non-canonical splice sites within these environmental samples.

The results highlight the complex genetic diversity present in marine organisms and emphasize the importance of studying the underexplored marine environment, as it represents a significant source of novel genetic information. Research into non-

canonical introns will improve our understanding of evolution in marine ecosystems, contributing valuable knowledge to the study of marine biodiversity.

Genome of the Amazon Guppy (*Poecilia bifurca*) reveals conservation of sex chromosomes and dosage compensation

Fong L¹, Johnson B¹, Darolti I², Sandkam B³, Mank J¹

¹University of British Columbia, ²University of Lausanne, ³Cornell University

POSTER SESSION 3 - **P03.077**, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

The Amazon guppy, *Poecilia bifurca*, is a small live-bearing fish. Related species, such as *P. reticulata*, *P. picta* and *P. parae* all share the same sex chromosome system, but with substantial diversity in the degree of Y degeneration and the extent of X chromosome dosage compensation. We built a female (XX) draft genome with 55X coverage of PacBio HiFi data, resulting in a 785 Mb assembly with 94.4% BUSCO

completeness. We used this genome to determine that *P. bifurca* shares the same sex chromosomes as related species, and that it exhibits substantial Y degeneration. We combined this with RNA-Seq data to reveal that *P. bifurca* also exhibits complete X chromosome dosage compensation. We further identify 11 putative autosome-to-Y gene duplications, five of which show gene expression in guppy male germ cells.

Lineage-specific selection and gene family dynamics in the genus *Lynx*

POSTER SESSION 3 - P03.083, EXPO AREA, August 21, 2025, 5:00 PM - 7:00 PM

Background: The investigation of species divergence and associated adaptations has remained a fundamental focus of evolutionary studies. Among mammals, the Felidae family is characterized by a rapid radiation, and a notable history of hybridization events among species. Within this felid family, the lynxes stand out as a globally distributed genus, comprising four species characterized by distinct ecological traits. In this study, we investigate the adaptive evolution in the *Lynx* lineage by integrating analyses of positive selection in protein-coding genes and gene family evolution dynamics.

Materials and methods: We leveraged recent high-quality genome assemblies for all four *Lynx* species to investigate patterns of adaptive evolution. To detect signals of positive selection, we applied codon substitution models to both the *Lynx* genus branch and each extant species-specific branch. From the Felidae phylome—comprising 14,738 coding sequences across 16 felid species—we identified 9,290 one-to-one orthologous genes. Positive selection was inferred using the branch-site model in codeml (PAML), considering only genes with significant support for both site and branch effects (BEB > 0.99 and LRT p-value < 0.05). These candidate genes were then subjected to Gene Ontology enrichment analysis using the topGO R package to identify overrepresented biological processes. In parallel, we explored gene family evolution using Count, analyzing a dataset of 13500 gene families. Gene family expansions, contractions, gains, and losses were inferred under a maximum likelihood birth–death model, and only lineage-specific changes with a posterior probability greater than 0.9 were retained.

Results: We identified lineage-specific signals of adaptation. In the ancestral *Lynx* genus
